Prognosis—This covers two phases The acute attack and the rheumatic heart disease The mortality from the first varies between 1 and 4 per cent and is practically always due to acute carditis occasionally accompanied by hyperpyrexia which is an ominous manifestation About puberty many children with badly damaged hearts succumb apparently because the hypertrophied organs cannot respond further to the rapid body growth With puberty however many patients develop some unknown type of resistance so that rheumatic recurrences are much less frequent than in childhood Indeed in each decade of life the liability to contract the disease and to develop permanent cardiac damage diminishes Chorea alone indicates a mild infection but chorea or subcutaneous nodules increase the gravity of the outlook Subcutaneous nodules are indicative of cardiac involvement but not necessarily fatal In general severe acute attacks damage the heart more than mild ones and polycyclic and continuous courses more than monocyclic Pericarditis indicates a severe pancardiac involvement

Several statistical studies indicate that the average life of patients with definite rheumatic heart disease is thirteen to fifteen years with shorter average duration for those who first developed the disease in childhood The ultimate prognosis is somewhat proportional to the severity of the cardiac damage and to the frequency of recurrence of attacks of rheumatic fever A patient who has suffered one attack of the *disease is three or four times more* liable to have rheumatism again if he contracts a streptococcal infection than is one who has never had rheumatism hence the importance in ultimate outcome of the prevention of streptococcal infections either by living under a better environment or by chemoprophylaxis

Treatment—Most important is the understanding by the physician of the nature of the malady and the action of the therapeutic agents This is particularly true with rheumatic fever because of the different clinical types protean manifestations implication of important viscera and the existence of drugs favorably *influencing* symptoms without eliminating the causative agent Systematic documenting of the various features is most helpful in picturing the

course of the infection, the importance of recognizing this cannot be overemphasized for it is obviously more reprehensible to allow a patient with active carditis to exercise too soon than to keep him inactive too long If significant records of these patients were kept we would hear less often 'The patient recovered two months ago from rheumatism but now is suffering from endocarditis

Rest relief of pain attention to nutrition and regulated convalescence are the chief therapeutic indications With acute polyarthritis rest is enforced by pain when pain disappears rest must be insisted upon by the physician While fresh air is beneficial the patient should be guarded from chilling which easily occurs because of the severe perspiration requiring frequent changes of the bed linen and patient s clothing Frequent bathing and dusting with some absorbent powder helps to prevent maceration of the skin Swathing the affected joints with flat pads made of cotton covered with gauze affords much comfort The support of the limbs by pillows so placed as partially to flex the joints provides the most comfortable position

Large amounts of fluid should be given to encourage the elimination of toxic substances and to replace water lost in sweating A high caloric diet composed of easily assimilable food should be provided often it is necessary to cater to the patient s taste in order to maintain nutrition During convalescence it can be coarser and more varied than at the time of high fever During the acute phases at least double the basic amount of the vitamin B complex and vitamin C should be furnished and probably three or four times the usual requirement of vitamin A

Drug Treatment —Practically all of the acute distressing symptoms except those due to cardiac failure are relieved by the *compounds of salicylic acid* These act as antipyretics and analgesics when given properly The therapeutic and toxic doses are close together hence the attendants should watch for the first symptoms of salicyl intoxication These are ringing in the ears deafness nausea vomiting and rarely delirium renal irritation must be detected by examination of the urine Sodium salicylate dissolved in water or in capsules or acetylsalicylic acid (aspirin) should be given in doses of 1 to 1.3 Gm (15–20 grains) every hour for from 8 to 10 doses or discontinued sooner if toxic symptoms appear The next day three fourths of the determined toxic dose may be given and following this the drug continued at about the same rate It should be continued until all signs of active infection have been absent for a week or ten days If well tolerated it should then be decreased gradually with constant watch for symptoms of relapse If these recur the dose must be increased The administration of sodium bicarbonate with salicylates is mainly to prevent gastric irritation but the bicarbonate should not be given in doses large enough to induce alkalosis Acetylsalicylic acid (aspirin) tablets are very irritating to an empty stomach much less so to one containing food The rectal administration of 120 to 180 cc of 2 per cent solution of sodium salicylate (10 grains to 1 ounce of water) two or three times daily is sometimes well tolerated when the drug given by mouth leads to nausea If rectal irritation results a weak starch solution as a vehicle may be substituted for the water Intravenous administration of salicylates has no special advantage

Neocinchophen once widely recommended has no special merit over the salicylates and is much more expensive

Aminopyrine (pyramidon) has antirheumatic effects similar to those of salicylates and acts more promptly in smaller doses It usually has few if any toxic side actions hence is specially useful in the presence of gastric irritability especially that due to heart failure from very active rheumatic carditis Its capacity to induce agranulocytosis occasionally makes it necessary to do fairly frequent leukocyte counts If the white blood cells drop to 4000 or 5000 per c mm the aminopyrine should be immediately stopped Probably agranulocytosis occurs in subjects with an idiosyncrasy to this drug and is more frequent in older persons with wasting diseases than in the young Aminopyrine is given in doses of 0 3 to 0.5 Gm (5 to 7 5 grains) four to six times daily with some doses during the night The total dosage should be sufficient to control the acute attack and after this

end has been attained the dosage may be reduced to a point just above that necessary to control the symptoms

Antistreptococcal Drugs—The sulfonamides so useful in many acute hemolytic streptococcal infections do not favorably influence the course of established rheumatic fever Sulfanilamide in fact, eems to aggravate the rheumatic symptoms The prophylactic action of these drugs is discussed later

Morphine or *codeine* is sometimes required to control pain especially thoracic

Digitalis should be given for heart failure as soon as signs of this appear Auricular fibrillation with active carditis usually calls for this drug as does a continuous cardiac rate of 130 or more A standardized preparation should be employed and therapeutic digitalization should be attained by giving 4 cat units the first dose 2 units after four to six hours and 2 units the next day if signs of overdigitalization are absent Maintenance dosage consists of ½ to 1½ cat units occasionally more per day Signs of overdigitalization are nausea vomiting extrasystoles especially in coupled beats Not infrequently both antipyretic drugs and digitalis are required to render comfortable a patient with active carditis

The treatment of complications follows symptomatic indications Severe precordial pain can often be alleviated by a light icebag over the painful area at other times heat furnishes more relief If the heart s action is much embarrassed by excessive pericardial exudate removal of the fluid sometimes is useful but as a rule this fluid is absorbed spontaneously Likewise it is necessary to remove pleural fluid only when the breathing space is much diminished

Serum Treatment—The parenteral injection of antistreptococcal horse or beef serum has been not only useless but at times has given rise to increased fever tachycardia dyspnea cyanosis and pulmonary congestion occasionally to severe arthritis Possibly a specific serum of the type homologous to the streptococcus infecting the patient might effect a cure but there are no therapeutic trials of this nature There is no convincing evidence that the serum of patients who have recovered from rheumatic fever has any beneficial effect

Nonspecific Shock and Fever Therapy—Some observers have noted a rapid recovery following various forms of nonspecific shock treatment L P Sutton noted rapid recovery from chorea following intravenous injections of typhoid vaccines and later showed that the beneficial effect was due to high fever which could be induced in hot boxes heated with carbon filament lamps or in a Kettering apparatus Some suggestive improvement following heat therapy was also recorded in patients with chronic carditis or subcutaneous nodules

Intravenous Vaccination with Streptococcal Vaccines—This treatment was based on the hypothesis that part of the rheumatic manifestations were due to a hypersensitive state of the patients tissues to streptococcal products and also on the observations that rabbits with induced hypersensitivity to streptococci could be best rendered hyposensitive by intravenous immunization In acute rheumatism both focal and general reactions induced by relatively small amounts of these vaccines can be prevented by antirheumatic drugs and the patients can be made tolerant to many times the original symptom inducing dose by suitable intravenous vaccination In animals it was later shown that such desensitization was closely related to the type specificity of the streptococci employed to sensitize them As many types of Group A streptococci cause the disease precursory to the rheumatic fever the entire subject of immunization and desensitization of rheumatic subjects must be restudied

Convalescence—During this period the greatest care must be exercised The rate of recovery is roughly proportional to the length and severity of illness The patient should remain in bed until free from fever and other signs of infection for two or three weeks without being under the influence of antipyretics The weight should have returned to normal the heart rate be fairly slow leukocytosis should be absent and the erythrocyte sedimentation rate should be below 15 to 20 The period of sitting in a chair should be slowly increased until he can sit up four or five hours a day without undue fatigue or reawakening the infection Then walking may be permitted a few steps at first then gradually increased Stair

climbing should not be permitted until walking on the level can be done without undue reaction A good guide to the effect of exertion is gained by noting the pulse rate immediately before exercise, immediately after and five minutes later if it is then not increased over the original rate increased exertion may be permitted if it is more rapid exercise should be diminished Reappearing signs of infection demand a return to complete rest The principles to follow are the physical retraining of a person whose heart has probably been diseased and in whom reinfection may cause further cardiac damage

Prophylaxis —As a guiding principle it now seems safe to assume that the prevention of Group A hemolytic streptococcal infections will prevent rheumatic fever While the practical attainment of the first leaves much to be desired still something may be accomplished by intelligently aimed efforts As the degree of progressive rheumatic heart disease is roughly proportional to the number and severity of recurrences of rheumatic fever prophylactic efforts are justifiable

A person who has recovered from rheumatic fever should avoid contact with patients having streptococcal infections and should be removed from such an environment The common use of dishes towels or other possibly contaminated objects should be avoided and the nature of air borne infections should be kept in mind Where it is possible to move a specially susceptible rheumatic subject to a southern climate this may be of value provided that environment insured freedom from exposure to streptococci otherwise it is of little value

Chemoprophylaxis —A patient with an acute hemolytic streptococcal infection treated with sulfonamides may develop rheumatic fever On the other hand there is now convincing evidence that they are efficient prophylactic agents of hemolytic streptococcal infections and when such infections are effectively prevented in previously rheumatic subjects there are no rheumatic recurrences The usual procedure has been to administer sulfanilamide daily in doses of 1 to 2 Gm from September to June the season of greatest danger and to maintain a blood level of 1 5 to 2 0 mg per cent While sulfathiazole and sulfadiazine have been used to a less extent they appear to have a similar prophylactic action and the latter may be the drug of choice because of lower toxicity The toxic by effects of these drugs make necessary their discontinuance in some cases All patients under going such chemoprophylaxis must be constantly under observation and have regular blood counts and urine examinations Any persistent toxic effect is an indication for stopping the drug

It has been suggested that continued administration of salicylates to a patient with a streptococcal infection might prevent an attack of rheumatic fever While there is little doubt that symptoms of rheumatism might be prevented just as they are alleviated after appearing there is as yet no satisfactory evidence of the suppression of a true rheumatic recurrence

Tonsillectomy —Our modern concept of the etiologic role of streptococcal infections gives us a more rational attitude towards the prophylactic effect of tonsillectomy The removal of tonsils may diminish a person s chances of acquiring such an infection but the fact that a very slight streptococcal infection of the nasopharynx may induce a rheumatic recurrence shows how ineffective a tonsillectomy may be in this respect There is still much lymphoid tissue left in the naso and oropharynx to harbor streptococci The question of tonsillectomy should therefore be considered from the standpoint of the patient s general health and its bearing on the rheumatic process and not on the rheumatic process alone Tonsils should not be removed during the acute phases of rheumatic fever, and prior to tonsillectomy a rheumatic subject should be given some sulfonamide preferably sulfadiazine to kill off any microorganisms that might enter the blood stream during the operation

THE ERYTHEMAS

Definition —The term erythema signifies a blushing This heading covers a somewhat indefinite group of diseases in which the essential clinical picture is a redness or hyperemia of the skin

The lesions of the erythemas assume various forms They may occur as either a localized or a generalized blushing of the cutaneous surface or as a number of more or less circumscribed areas of hyperemia sometimes with raised surfaces and sometimes in patterns In generalized erythema the face trunk upper arms and thighs are more frequently involved than other parts of the body

Etiology —*External Causes* —The erythemas due to external causes are generally confined to areas of the body directly exposed to an irritant These irritants are either physical or chemical in nature Among the physical are friction pressure heat sunlight roentgen rays and radium among the chemical are acids alkalis turpentine mustard insect stings poisons of plants and septic discharges Skin conditions caused by the poisons of plants are generally designated as *erythema venenatum*

Internal Causes —One of the most frequent causes of erythema is hypersensitiveness to certain foods particularly shellfish and berries Drugs such as atropine chloral hydrate quinine sodium salicylate and mercury occasionally produce an erythema in patients with an idiosyncrasy to them *Erythema medicamentosum* is a name sometimes applied to an erythema caused by drugs Bacterial toxins injected serum and toxic products absorbed from the gastrointestinal tract may also produce an erythema

Pathology —The histologic feature of prime importance is dilatation of the capillaries In some cases there may be also an exudation of serum leukocytes or even of red blood cells into the surrounding tissue

Signs and Symptoms —Hyperemia as evidenced by redness of the skin is the most important finding in erythema In this condition the color disappears on pressure and reappears when the pressure is withdrawn Tenderness a burning sensation and itching are often present A severe erythema is frequently followed by desquamation and pigmentation The eruption is generally of short duration

Constitutional symptoms such as fever and malaise are either entirely absent or very mild

Diagnosis —Erythema due to external causes is generally recognized by a history of exposure to some skin irritant Erythema due to internal causes is sometimes more difficult to diagnose although a history of having taken some drug or particular food to which the patient has an idiosyncrasy or a history of infection, or of a gastrointestinal disorder may serve as a clue to the nature of the condition

Lack of constitutional symptoms is an important feature in making a diagnosis of erythema

Treatment —The most efficacious treatment for erythema consists in recognizing its cause and treating that Local irritation may be relieved by the application of a simple dusting powder or by sponging the skin with a weak solution of sodium bicarbonate alcohol or boric acid in water Analgesics such as sodium salicylate or acetylsalicylic acid are sometimes indicated and rest in bed is generally advisable The use of soaps and other substances irritating to the skin should be discontinued

Several forms of erythema are worthy of mention

W J STAINSBY

ERYTHEMA MULTIFORME
(*Erythema Exudativum Multiforme*)

Erythema multiforme as the name implies is distinguished by the varied aspects of its lesions—two cases seldom being alike The eruption may be macular papular circinate bullous or hemorrhagic As a rule it is symmetrically bilateral with a predilection for the face neck arms legs and dorsal surfaces of the hands and feet Mucous membranes may also be involved In the past a host of names such as erythema papulatum and erythema annulare have been employed to designate different types of this disease An elaborate classification serves no useful purpose and merely tends to confuse rather than to clarify the subject as the etiology distribution of the eruption and course of the disease are similar regardless of the type of the lesion

Symptoms —In erythema multiforme constitutional symptoms are either entirely absent or are very mild varying somewhat with the underlying processes In some cases there is a mild fever and in a few malaise The pathologic picture is similar to that already described under erythema

Etiology —The etiology of erythema multiforme is unknown—some investigators associate it with foci of infection in the teeth tonsils sinuses or uterus while others associate it with the absorption of toxic products from ingested foods The disease is known to be particularly prevalent in the spring and autumn which is sometimes thought to indicate that dampness and rain or changing temperatures play a part in its etiology

Prognosis —Erythema multiforme as a rule runs a course of a few days to two or three weeks Rarely it may last for several months Some patients have a recurrence every spring or every spring and autumn

Diagnosis —Erythema multiforme must be differentiated from the maculopapular syphilide and from ringworm pityriasis rosea pemphigus dermatitis herpetiformis and lupus erythematosus Erythema multiforme is distinguished by its comparatively short duration and the absence of any tendency to form adherent scales or to permanently injure the skin

Treatment —The treatment for erythema multiforme is similar to that already described under erythema Attempts should be made to determine its etiology if possible and by correcting that to eradicate the condition

W J STAINSBY

ERYTHEMA NODOSUM

The eruption erythema nodosum consists of poorly defined nodular lesions varying in diameter from a few millimeters to 5 or 6 cm The lesions are prone to appear on the shins but may occur on any of the extremities or on the buttocks The skin over the nodules is smooth shiny and generally of a rose-red color Ulceration seldom takes place The nodules appear in crops last from a few days to several weeks and slowly disappear

In erythema nodosum the eruption is usually preceded by mild constitutional symptoms such as fever malaise and pain in the muscles and joints, and is sometimes accompanied by definite polyarthritis

Etiology —Erythema nodosum does not have a specific etiology and it is now generally considered that almost any infectious disease may produce the condition The outstanding sources are rheumatic fever tuberculosis syphilis and infections caused by the gonococcus and meningococcus

Histologic examination of lesions of this disease show that there is dilatation of the capillaries and extravasation of serum leukocytes and erythrocytes into the surrounding tissues The bruised appearance which the lesions assume on healing is due to the disintegration of red blood cells

Treatment —In the treatment of erythema nodosum emphasis should be placed on an effort to determine the etiologic factors underlying the condition and to correct or remove them Analgesics especially salicylates are useful when the eruption is accompanied by pain Soothing lotions as previously described may be applied locally

W J STAINSBY

ERYTHEMA INFECTIOSUM

Erythema infectiosum is a mildly contagious disease that produces a generalized erythema of the cutaneous surface that often

varies in appearance with individual cases but which when typical is characteristic of the disease The condition begins insidiously with a dusky flushing of the cheeks which is soon followed by a generalized erythema which is more marked on the buttocks and extremities than elsewhere Associated with the erythema there are always more or less well defined macular and papular lesions The generalized erythema lasts for several days to a week when the lesions disappear from the trunk but persist for an additional week or more on the arms and the legs

When the lesions on the arms are well defined, no mistake can be made as to the nature of the condition The rash starts there as a small area of erythema with a sharply defined edge that gradually spreads peripherally clearing up completely in the older parts of the lesion When an area such as this coalesces with other areas developing in the same manner one sees an arm that is covered with irregular serpiginous lines winding about the arm and surrounding small areas of normal appearing skin

There are no generalized symptoms other than slight malaise and sometimes mild tickling or burning of the skin The disease is uncommon

Etiology —The infecting agent is unknown and the incubative period is from four to fourteen days

Differential Diagnosis —Erythema infectiosum must be differentiated especially from rubella measles and scarlet fever This can usually be done by the characteristic appearance of the rash particularly on the arms and the almost complete absence of symptoms other than those produced by the skin lesions

Treatment —None is indicated No fatalities have been reported Isolation aids in preventing a spread of the condition but the disease is so mild that insistence on such a course is unnecessary

W J Stainsby

ERYTHEMA INDURATUM

(Bazin s Disease)

Erythema induratum appears as a localized red or violet discoloration of the skin that gradually turns brown Associated with the color changes there develop in the cutis or subcutaneous tissues freely movable nodules that may vary in size from a few millimeters to several centimeters in diameter The nodules sometimes ulcerate leaving shallow craters covered with a serous rather than a purulent exudate These ulcers are regular in outline and their edges are not undermined The condition is usually bilateral with a predilection for the calves of the legs, although the face, trunk and arms are sometimes sites of the lesions Females are much more frequently affected than males

Etiology —Erythema induratum is caused by the tubercle bacillus but it must be remembered that syphilis and leprosy can produce similar clinical pictures

Treatment —Treatment consists of rest of the part affected, elevation of the extremity, and localized support by means of bandages The disease tends to heal slowly but scarring usually results

W J Stainsby

ERYTHEMA OF THE NINTH DAY

Erythema of the ninth day is a term applied to a generalized erythema that occasionally occurs following the administration of arsphenamine or neoarsphenamine More recently reports have appeared in the literature which indicate that this condition can develop following the intramuscular injection of bismuth It occurs from eight to ten days following the injection of the drug with an average of nine days from which the term is derived It is a self limited mild reaction and the nature of the condition is not clearly understood Recognition of the symptom complex is important so that it will not be confused with the more serious arsenical dermatitis

Treatment —Usually none is required The condition remains only a short time and is definitely self limited Arsenicals may again be injected as soon as the rash has cleared

W J Stainsby

SARCOID OF DARIER ROUSSY

This type of sarcoid differs from Boeck's sarcoid in that the lesion lies chiefly in the

subcutis rather than in the cutis There is an infiltrative thickening of the skin and subcutaneous tissues and the color varies from that of normal skin to a pinkish or rose color Nodules varying in size up to 2 cm in diameter appear and are located in the subcutaneous structures and tend to arrange themselves in columns or strings While any part of the body may be involved the disease tends to attack the trunk particularly the buttocks

Histology —The lesion is made up of areas of epithelioid cells which lie in the subcutis with strands radiating to the cutis and fatty tissues Along with the epithelioid cells are a varying amount of connective tissue *lymphocytes and giant cells*

Etiology —The etiology is not definitely established but the tubercle bacillus has been suspected as an etiologic agent by several investigators of the disease

Treatment —X ray therapy may be tried and some patients have been benefited by this form of treatment

SARCOIDOSIS

(Boeck s sarcoid Lupus pernio Benignes Miliar lupoid Benign lymphogranulomatosis Osteitis tuberculosa multiplex cystoides Mortimer s malady Hutchinson Boeck s disease Maladie de Besnier Boeck Besnier Tenneson s disease Schaumann s disease Uveoparotid fever or Heerfordt s disease)

Definition —Sarcoidosis is a chronic indolent and benign infectious disease of unknown cause involving the skin lymph nodes eyes salivary glands lungs and bones of the hands and feet especially In addition to these conspicuous lesions disseminated systemic manifestations bespeak widespread pathological changes The predominance of certain lesions has perpetuated as clinical entities such groupings of clinical details as uveoparotid fever

Etiology —Tuberculosis has been cited as the underlying cause of sarcoidosis by most observers Acid fast organisms have at times been seen in the lesions but Koch s postulates have not been fulfilled in any further detail Furthermore the reactions to large doses of old tuberculin are conspicuously feeble or negative Singularly the lesions of sarcoidosis disappear upon the development of active tuberculosis Some maintain that the products of the *Mycobacterium tuberculosis* rather than the organism itself may be responsible for the disease

The *Mycobacterium leprae* has received some attention in this connection The difficulty in cultivating the acid fast bacilli from the sarcoid lesions and in reproducing the disease might well raise this question but with certain similarities in the cutaneous and bony manifestations of the two diseases the clinical resemblance ceases A filtrable virus has been incriminated on the basis of a Frei reaction following the intracutaneous injection of an emulsion of a sarcoid nodule into an affected subject Obviously further support must be marshalled before admitting such evidence for a virus etiology

Sarcoidosis may occur at any period of life but usually in patients between fifteen and forty years of age The rare occurrence of this disease in siblings does not favor a familial or a communicable basis Sex exerts no influence In this country there is an apparent predilection for the Negro but no race is exempt from its inroads Sarcoidosis appears more commonly in rural than in urban dwellers Most instances of the disease have been reported from the north temperate zone especially in Scandinavia northern Europe England and North America

Morbid Anatomy —The fundamental

lesion is granulomatous Large pale epithelioid cells are collected in isolated nests or well defined nodules As a rule, these areas are not sharply demarcated from normal tissue Occasional pale multinucleated giant cells complete the picture Neither necrosis nor caseation is observed The sluggishness of the process is significant Months may pass without perceptible histologic change In its natural evolution fibrosis may be anticipated These lesions have been found in the skin breast mucous membrane salivary gland lachrymal gland lymph node tonsil eye nervous system pituitary body, thyroid gland heart lung serous membrane *liver intestine spleen kidney, endometrium* prostate testis, epididymis voluntary muscle tendon sheath and bone The bone marrow and the Haversian canals have been found infiltrated by the characteristic epithelioid cells in sarcoidosis

Pathologic Physiology —The manifestations of disturbed function may be as wide spread as the lesions of sarcoidosis Xerostomia may attend the active phase of the uveoparotid syndrome but permanent alteration of salivary function is rare Visual disorders in this syndrome may be persistent and occasionally permanent difficulties even as serious as blindness may result Invasion of the pituitary body has given rise to diabetes insipidus Myxedema may arise from thyroid involvement Extensive pulmonary sarcoidosis may lead to polycythemia right heart strain and overstrain (chronic *cor pulmonale*) Tachycardia arrhythmia and heart failure have been attributed to cardiac invasion by this process The hyperglobulinemia may reflect the hepatic phase of the disease Renal involvement rarely advances to the degree of frank uremia but altered glomerular function is indicated by occasional albuminuria and hematuria Eunuchoidism may attend testicular encroachment

Symptoms —The patient suffering from sarcoidosis experiences slight constitutional reaction as a rule Fever is unusual Even major degrees of pulmonary involvement may occur without any accession of temperature Mild malaise and indisposition may appear Distaste for food vague gastric symptoms and diarrhea occasionally supervene Night sweats and arthralgia have been noted So insidious may be the onset that only the cutaneous eruption or the lymph adenopathy arouses clinical suspicion as to the true state of affairs The skin lesions appear in about 50 per cent of patients with sarcoidosis Boeck's description of three characteristic eruptions still pertains (1) Small firm cutaneous nodules (klein knotige) may be noted in the butterfly area of the face on the arms and back These nodules are sharply demarcated smooth brown or blue (2) Similar but larger nodules (grossknotige) may appear (3) The skin may be diffusely infiltrated and thickened (Lupus pernio) over the nose face and ears The tense skin over the affected *area* may be bluish but tiny yellow granules appear at the margins This eruption is not painful nor attended by pruritus Having reached its peak there may be no change for months Atrophic scars may mark the sites of earlier lesions but ulceration never occurs The mucous membranes of the nose and oropharynx may be reddened and nodular

The *involvement* of the *hands* serves as a clue to the diagnosis Firm nodules appear at the interphalangeal joints These may present a remarkable symmetry A knotty appearance may be imparted to the affected fingers and hands Scaling of the skin occurs over these projections The subject complains of tightness or stiffness of the fingers but they are not painful or tender General lymphadenopathy may early attract the attention Pre- and post auricular involvement is particularly significant The cervical submaxillary axillary epitrochlear and inguinal nodes may be involved As a rule the individual nodes are not especially large but there are exceptions These nodes are firm in consistency discrete and non tender Pressure symptoms rarely arise from them Cough dyspnea and remittent low grade fever may attend mediastinal or pulmonary involvement but extensive intrathoracic invasion may occur without significant subjective or objective evidence Interscapular dulness and bronchial breath sounds are occasionally elicited At times the pulmonary process may be so extensive as to lead to right heart embarrassment Hepatomegaly and splenomegaly may arise from sarcoid involvement of these organs

Uveoparotid fever constitutes an expres

sion of sarcoidosis requiring especial attention Insidiously as in the commoner forms of sarcoidosis the picture is evolved after non specific prodromes of lassitude drowsiness malaise and indefinite gastro intestinal symptoms Intermittent pyrexia of moderate degree may attend Firm painless swelling of the parotid glands usually precedes ocular involvement Although bilateral in a vast majority the invasion of the parotid glands is not simultaneous Dryness of the mouth may be a distressing symptom Mastication is not embarrassed by the parotid swelling The induration of the glands may be permanent Occasionally the ophthalmic symptoms anticipate the parotitis Uveitis is the most common detail of this picture but there have also occurred conjunctivitis corneal herpes keratitis corneal opacities vitreous hemorrhage optic neuritis neuroretinitis chorioretinitis glaucoma aqueous turbidity and cataract Relapses are not infrequent The third component in the uveoparotid syndrome is the cranial nerve involvement A majority of these patients develops seventh nerve paralysis unilateral or bilateral quite suddenly a few days to a few months after the onset of the parotitis The lower facial distribution is more involved than the upper Usually the facial palsy subsides *pari passu* with the parotitis but it may appear after its subsidence Occasional neurologic involvement of different orders may be observed such as paralysis of the soft palate dysphagia intercostal neuralgia paralysis of the vocal cords deafness ptosis of the eyelid wasting of the muscles of the hand loss of vibratory perception in the legs and polyneuritis

A slight hypochromic microcytic anemia may be anticipated in sarcoidosis The leukocytes are normal in number or there may be a slight leukopenia Monocytosis prevails Eosinophilia of a slight to moderate degree (up to 35 per cent) may occur in a minority Increased sedimentation speed is the rule The Wassermann reaction is negative The blood calcium and phosphatase are quite regularly increased and the blood phosphorus and cholesterol normal The total plasma proteins are increased largely by reason of the increase in the plasma globulin The albumin/globulin ratio is frequently reversed In the uveoparotid syndrome there may be added pleocytosis and increased protein in the cerebrospinal fluid The x rays of the chest may disclose two fundamental types of intrathoracic involvement Tracheobronchial and mediastinal lymphadenopathy may assume varying proportions From the hilum there may occur an extension along the peribronchial structures to involve the lung in an advancing process of fibrosis that fades centrifugally Patches of fibrous density may be scattered irregularly through the lung These changes are most marked at the bases In the second type of pulmonary sarcoidosis a reticular appearance is lent to the whole lung field and tiny densities stud the same to indicate a miliary distribution of the pathologic process Particularly significant is the x ray appearance of the shafts of the phalanges and metacarpal bones Without periosteal involvement or thickening rarefaction of the medullary portion of these bones takes place Eventually small punched-out areas appear in the small bones of the hands and feet (ostitis tuberculosa multiplex cystoides) Less commonly the long bones of the arms and legs are involved Sarcoidosis of the skull has been reported The bony changes are more extensive than are disclosed by the x ray Biopsies of the sarcoid lesions of the skin parotid tonsil and bone marrow are recommended in a diagnostic survey but the tonsil is not so regularly the seat of the pathologic changes as was once thought

Diagnosis—The diagnosis of sarcoidosis is usually made from the nature of the cutaneous eruption and the lymphadenopathy with or without the support of x rays of the thorax and hands Hutchinson s description of the skin lesions is significant in this relation The disease is characterized by the formation of multiple raised dusky red patches which have no tendency to inflame or ulcerate They are very persistent and extend but slowly They occur in groups their bilateral symmetry and the absence of all tendency to ulcerate or form crusts are features which separate the malady from lupus vulgaris To none of the other forms of lupus has the malady any resemblance' The uveoparotid syndrome adds the parotid tumor uveal tract involvement and facial palsy Invasion of the lachrymal and salivary glands may satisfy the diagnostic cri

teria of Mikulicz s syndrome Only blood studies and biopsy of the affected structures will properly catalogue its several origins General lymphadenopathy and splenomegaly may lead to the suspicion of Hodgkin's disease or hyperplastic tuberculosis The singular absence of constitutional symptoms and the sluggish course in sarcoidosis contrast to the rule in Hodgkin s disease and tuberculosis The degree and order of the pulmonary involvement upon x ray study contrast strikingly with the clinical well being of the patient with sarcoidosis This circumstance alone militates against the diagnosis of Hodgkin's disease and tuberculosis The negative Mantoux reaction and persistently negative sputa would be further evidence against a tuberculous explanation X ray of the hands should give the clue in a considerable proportion of the doubtful diagnoses The absence of periosteal change would rule out syphilis as well as tuberculosis The negative Wassermann reaction would be helpful The virtual absence of constitutional symptoms and the benign course exclude leprosy The industrial history might afford the answer to a possible confusion with silicosis Biopsy of accessible lesions would arbitrarily rule out Hodgkin's disease and lymphosarcoma but there might be raised the question of tuberculosis which may be met as stated Although the differences between tuberculous or syphilitic iridocyclitis and the uveitis of uveoparotid fever may be finely drawn parotitis and facial palsy are peculiar to the latter Furthermore a positive Mantoux reaction on one hand or a positive Wassermann reaction on the other would establish the respective etiologies

As the diagnostic horizon is lifted an extension of sarcoidosis to include a number of systemic disorders such as regional ileitis may increase the problem

Prognosis.—Although interrupted by relapses the course of sarcoidosis is singularly benign and free from grave constitutional symptoms Spontaneous recovery may be anticipated in a majority of these patients The pathologic lesions tend to heal by fibrosis Atrophic scars may mark obsolete cutaneous eruptions The lymph nodes become more dense Although the symptoms of the uveoparotid syndrome usually disappear entirely some induration of the parotid gland and more or less serious visual disturbances may persist The pulmonary changes may lead to chronic *cor pulmonale* with congestive failure Approximately 10 per cent of these patients develop clinical tuberculosis Clinical abatement of cutaneous sarcoidosis has attended activation of pulmonary tuberculosis In the occasional instance of invasion of some important structure such as the pituitary body thyroid gland or heart by the granulomatous process replacement of essential parenchyma may determine serious collateral effects A mortality of 5 per cent is reported

Treatment—The therapy of a disease with such a natural history is difficult to evaluate No specific has been reported Tuberculin is no longer advocated in the treatment of sarcoidosis Arsenic has no established place although an occasional success has attended the use of neoarsphenamine Gold therapy is not recommended The earlier promise of ultraviolet rays has not been generally sustained but the lymphadenopathy may recede under its application X ray and radium therapy offer nothing Antileprol (a derivative of chaulmoogra) was once acclaimed but has fallen into disuse General hygienic measures alone prevail at the present time Since neither infectivity nor for that matter tuberculous etiology has been established sanatorium treatment should be discouraged

DISSEMINATED LUPUS ERYTHEMATOSUS

Definition—Among the heterogeneous group of so called rheumatoid diseases disseminated lupus erythematosus constitutes a disease entity distinguished by a prolonged clinical course which usually terminates fatally by a striking predilection for young females and by characteristic pathologic changes in the vascular system Because in many instances an erythematous rash is apt to appear on the face and other parts of the body at some stage of the disease the condition was first described about the middle of the nineteenth century by dermatologists (Hebra Casenave Kaposi) who named it lupus erythematodes or erythematosus In spite of its name this disease bears no relationship whatever to tuberculosis and lupus vulgaris nor to that benign indolent skin lesion known to dermatologists as discoid lupus

In recent years it has been recognized that the skin rash is not invariably present and that when it appears it is a superficial manifestation of a widespread injury to the collagen which serves as a matrix and binding substance for capillaries and other small blood vessels in various parts of the body The appearance of an erythema spreading in a butterfly pattern across the bridge of the nose and the malar eminences in a patient suffering from fever and the other systemic manifestations of this disease greatly facilitates the diagnosis But even in the absence of the rash the characteristic combination of other clinical manifestations should be adequate for the diagnosis On the other hand an erythema on the bridge of the nose and the malar eminences may be due to a variety of other causes and it alone does not warrant a diagnosis of disseminated lupus erythematosus if fever and the other clinical features of this disease are absent

Incidence—The disease is still unfamiliar to many clinicians not so much because of its rarity as because the patient is usually under the care of a dermatologist for the rash One of the most remarkable characteristics of the disease is its sex linkage, twenty two out of twenty three cases reported by Baehr Klemperer and Schifrin in 1935 were females eighteen were in the second and third decades of life all but one were between puberty and the menopause the youngest being seven years old the oldest forty five

Etiology—Bacteriologic studies have as yet revealed no clue concerning the cause of this disease Blood cultures are negative unless there is an intercurrent pneumonia or a terminal streptococcus or staphylococcus blood infection In spite of the definite sex linkage no endocrine disease can be identified as a predisposing factor Nor do vitamin deficiencies seem to play even a contributory role As in rheumatic fever and rheumatoid arthritis infection is probably responsible for the disease but its nature has not yet been determined The special predisposition of females would seem to indicate that, whatever the exact nature of this infection or intoxication the disease is conditioned upon a peculiarity in the constitutional reaction of the host It seems to exhibit its effect primarily upon endothelium lined structures capillaries small arteries and veins the endocardium and the synovial and serous membranes

Morbid Anatomy—At the autopsy table the frequent paucity of severe gross anatomic changes and the absence of a distinctive lethal lesion is in striking contrast to the profound toxemia and the train of clinical events leading to the death of the patient It has been shown that the widespread and apparently heterogenous visceral lesions can be reduced to a common denominator Whether the basis of the disease be infection or profound alteration of tissue reactivity it can at least be stated that the con

stant site of the injury lies in the connective tissues of the body

Pericardial involvement occurs frequently and in its severest form appears as a thick, gelatinous, connective tissue completely obliterating the pericardial space This appearance is due to a series of proliferative and degenerative changes of the collagenous tissue underneath the mesothelium Pleuritis is also frequent and presents a picture similar to that of the pericarditis Perisplenitis and perihepatitis are common

The heart may be involved in all of its three layers In about 30 per cent of the cases examined grossly the *endocardium* exhibits a pathognomonic lesion first described by Libman and Sacks The endocardial vegetations may be small and verrucous or large broad and flat They are not limited to the closure lines of the valve cusps but are found elsewhere and on both sides of the leaflets They may extend down the chordae tendineae The mural endocardium of the ventricles is similarly involved A favorable localization is in the pocket between auriculoventricular valves and mural endocardium The lesion is not superficial but begins as a degeneration or necrosis of the subendothelial collagenous tissue of the endocardium The altered tissue becomes by swelling an excrescence on the surface of the endocardium Hence in an additional number of cases early endocardial involvement may be recognized microscopically in the absence of grossly visible lesions The most advanced endocardial lesions are prone to secondary bacterial implantation This when it does occur is either terminal or preterminal

Focal lesions of the interstitial collagenous tissue of the myocardium morphologically identical with those seen in the endocardium and pericardium are present in about 35 per cent of cases Aschoff bodies have not been found

The *kidneys* are generally large and smooth Not infrequently the surfaces show diffuse shallow scarring similar to the atrophy in malignant nephrosclerosis The renal glomeruli often exhibit a distinctive lesion The glomerular loops are thick rigid and deeply eosinophilic Because of their fancied resemblance to loops of bent wire these have been called 'wire loops The glomeruli also show focal necroses of loops These alterations are merely another local expression of the widespread damage to collagen

The small arteries and arterioles of various viscera and especially of the kidneys may show fibrinoid degeneration and necrosis originating in the connective tissue matrix of the vessel wall

An almost constant and characteristic lesion is seen in the *spleen* The central arteries are surrounded by rings of collagenous fibers The accretion of such sclerosing fibrous tissue rings is occasionally extraordinary The spleen itself is not particularly large the average weight being 260 Gm

Involvement of the widely dispersed system of *connective tissues* is exemplified in occasional profound alteration in the retroperitoneal and mediastinal tissues Histologically the changes here are similar to those observed in the pericardium In two cases observed by the author the esophagus was firmly fixed to surrounding structures as the result of this degenerative and productive process in the mediastinal tissues

In those areas of *skin* showing involvement the collagenous tissue of the upper corium exhibits degenerative changes culminating in the most advanced lesions in *fibrinoid degeneration* The smaller blood vessels may also participate The hemorrhages and the epithelial changes are probably secondary to these degenerative changes in the connective tissue

The *lymph nodes* which are enlarged in about one half the cases frequently exhibit focal necrosis Generalized *peritonitis* has followed the breaking down of secondarily infected mesenteric lymph nodes *Bronchopneumonia* is a frequent terminal complication

Symptoms —The salient clinical manifestations are (1) a prolonged irregular fever with a tendency to remissions of variable duration (weeks months or even years) (2) a tendency to recurrent involvement of synovial and serous membranes (polyarthritis pleuritis pericarditis) (3) depression of bone marrow function (leukopenia moderate hypochromic anemia moderate thrombopenia) and (4) in advanced stages clinical evidences of vascular alterations in the skin the kidneys and the other viscera

In the absence of the rash the condition may resemble an infectious polyarthritis The pain and sometimes swelling of various joints may at first make it difficult to distinguish the condition from rheumatic fever or from rheumatoid arthritis Suspicion may first be directed to its true nature by finding a leukopenia the white blood cell count usually ranging between 3500 and 6000 while the polynuclear leukocytes are proportionately reduced The characteristic leukopenia may be replaced by leukocytosis whenever *secondary intercurrent infections* occur such as bronchopneumonia As the disease progresses the hemoglobin falls more rapidly than the red cell count but rarely below 60 per cent In the more advanced stages the blood platelet count is apt to be depressed to about 100 000 occasionally as low as 40 000 Although syphilis is not a factor and the Wassermann test is usually *negative it may at times become positive* or anticomplementary in the later stages of the disease

Suspicion that the illness is not rheumatic fever or rheumatoid arthritis is warranted when red blood cells are found in the microscopic examination of the urine The presence of red blood cells in the urine is due to the development of renal vascular lesions a pathologic *alteration which does not* commonly occur in rheumatic fever without heart failure or in rheumatoid arthritis Small amounts of albumin are also usually to be found The appearance of large amounts of albumin red blood cells and casts resembling the urinary findings of an acute glomerulonephritis signifies the development of extensive vascular changes and of glomerular damage It occurs in the advanced stage of the disease and completely eliminates the diagnosis of rheumatic fever

In addition to arthralgia and arthritis attacks of pleurisy or of pericarditis may occur at any *time during the disease Probably* due to peritoneal serositis some patients may at times complain of abdominal pain and present abdominal distention and diffuse tenderness

When the fever is high and the patient s state is unusually toxic the heart is apt to have a gallop rhythm The electrocardiogram reveals no characteristic changes as a rule except low voltage In some patients a soft systolic murmur is audible at the apex of the heart or to the left of the sternum In most instances it is not to be regarded as evidence of endocarditis as it may be due to the effect of fever or of anemia If it becomes unusually conspicuous it may indicate the peculiar type of endocarditis (Libman Sacks) which develops in the advanced stage of the illness in about 30 per cent of the cases

Either at the onset or else sometimes at a later stage vascular lesions become visible

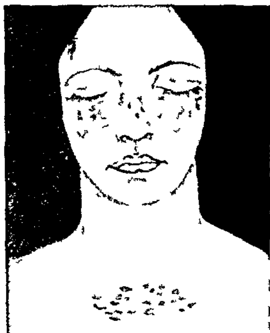

Fig 42—Typical butterfly lesion of lupus erythematosus on the bridge of the nose and the cheeks fading lesions on the exposed portion of the chest

on the skin as erythematous macules or patches which tend to become confluent The rash first appears as a rule upon the more exposed parts of the face the bridge of the nose and the cheeks above the eyebrows on the upper lip the prominence of *the chin and* the edges of the pinna It is also commonly found on the V shaped exposed area of the upper chest It may at times be characteristically located on the ends of the fingers and around the nail beds or as erythematous macules on the thenar and hypothenar eminences the palms occasionally on the ends of the toes and the balls of the feet Areas of skin on parts of the body which are subject to rubbing *or other*

mechanical trauma may become erythematous such as the elbows and knees the shoulders the malleoli the buttocks and the dorsal aspects of the forearms

If the rash has existed for some time minute telangiectases may be scattered in the midst of the erythema as evidence of more permanent vascular changes At times the intensely erythematous areas may present a purplish blush especially on the face fingers elbows and chest due to diffuse extravasations of red cells and plasma Small groups of purpuric or petechial hemorrhages are sometimes seen on the skin and mucous membranes at the height of the disease During periods of remission the erythema tends to disappear but macules of brown pigmentation will then persist in the previously affected areas

Some patients give a history of exposure to the sun immediately before the onset of the disease or of an exacerbation Others who have suffered mildly for weeks or months with a low grade fever and migrating arthralgia expose themselves to sunlight during convalescence and only then develop the facial rash followed by an exacerbation of the illness In other cases no history of exposure to sunlight is given

At the height of the disease erythematous or petechial macules may appear on the mucous membranes especially of the mouth which soon develop into shallow ulcers surrounded by an erythematous or hemorrhagic areola These lesions tend to heal In some patients the tendency to purpura may become marked both in the skin and mucous membranes due to the intense vascular injury and perhaps in part to a tendency to thrombopenia In a few instances hemorrhagic vesicles or even small hemorrhagic necroses develop on the intensely erythematous areas of the face or the hands

Aside from the skin and mucous membrane lesions the progressive injury to the peripheral vascular system results in microscopic hematuria and albuminuria which when marked may give rise to a suspicion of glomerulonephritis Severe examples of renal damage may be associated with fixation of specific gravity of the urine and sometimes in the last weeks of the disease azotemia In spite of severe vascular injury and the renal damage the blood pressure is usually normal sometimes moderately elevated Moderate edema of the face and extremities occurs at times due either to the diffuse vascular disturbance in the skin or to hypoproteinuria If prolonged albuminuria results in profound hypoproteinuria ana

Fig 43—Extensive spread of the rash of lupus erythematosus which at first had a typical butterfly distribution on the bridge of the nose and the cheeks In its advanced stage the rash covers almost the entire face but still does not involve the shaded areas of the face and neck Also characteristic is the V shaped area of erythema on the exposed part of the chest

sarca can develop as a rare terminal phenomenon

Some discrete enlargement of regional lymph nodes is common especially when the skin and mucous membrane manifestations are conspicuous The spleen may be palpable but it is usually not Ophthalmologic examination in advanced cases reveals characteristic evidences of vascular injury perivascular hemorrhages segmentation of arteries scattered fluffy exudates and at times circumpapillary edema and even flame shaped hemorrhages

the favorite remedy of dermatologists There is no reason to believe that it possesses any genuinely favorable influence upon the disease It is to be avoided because it may further depress bone marrow function it may increase the severity of the vascular lesions and it is certainly capable of increasing the severity of renal damage

Remissions in the disease have occurred in patients treated in a variety of ways Confinement to a darkened room or one in which the windows are covered with red cellophane seems to be helpful Although no

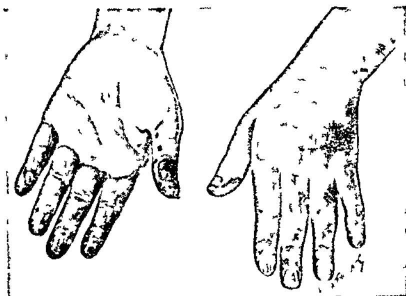

Fig 44—The skin lesions of lupus erythematosus may also occur on the hands and feet When present, the erythema commonly involves the palmar surface of the terminal phalanges and the area of skin around the nail beds on the sides and dorsum of the fingers In the midst of the erythema are petechial hemorrhages and telangiectases The blebs occur only rarely and in cases with the most intense skin lesions Scattered erythematous macules are sometimes observed on the palms on the thenar and hypothenar eminences

Prognosis—The fever and other manifestations of the disease may continue for many months with long alternating periods of exacerbation and of remission In some cases complete remissions may last for years but the ultimate prognosis is grave Occasionally a patient who has been critically ill for months may improve slowly and recover completely However most sufferers from this disease ultimately die Death is due to the toxemia of the disease to renal insufficiency (azotemia) or to an intercurrent pneumococcus streptococcus or staphylococcus infection

Treatment.—No form of specific therapy is available Gold chloride has long been

history of vitamin deficiency can be held responsible for the condition a high calorie diet with the addition of each of the various vitamins has been tried Nicotinic acid has failed to relieve the skin manifestations Most patients have a low blood level and a low excretion rate for cevitamic acid but the prolonged administration of generous amounts of this vitamin to the point of complete saturation does not affect the progress of the disease nor prevent the petechial lesions

Because of the susceptibility of girls and young women to the disease both estrogenic hormones as well as androgens have been employed including large doses of tes

tosterone propionate It is doubtful whether this form of therapy has been beneficial During active febrile periods, the administration of prophylactic doses of sulfadiazine 0 5 to 1 0 Gm twice a day may prevent the secondary infections Sulfanilamide and sulfapyridine in full dosages are indicated for the control of secondary infections with the *Streptococcus haemolyticus* and the pneumococcus They have no influence on the primary disease

INFECTIOUS MONONUCLEOSIS

(*Glandular Fever Benign Lymphadenosis Monocytic Angina*)

Definition—Infectious mononucleosis is an acute infectious and contagious disease of unknown etiology characterized by fever enlargement of the lymph nodes splenomegaly lymphocytosis and the presence of heterophile antibodies in the blood

History—Under the term Drusenfieber E Pfeiffer in 1889 described a benign epidemic disease in children featured by general malaise fever cervical adenopathy reddened throat without exudate enlarged liver and spleen The glands did not suppurate In 1920 Sprunt and Evans reported a group of benign sporadic cases in young adults characterized by acute onset with fever sore throat enlargement of the lymph nodes splenomegaly and a peculiar blood picture (mononucleosis) Tidy and Morley in 1921 established the identity of these two syndromes Longcope and Downey and McKinlay followed with confirmatory reports Glanzmann in 1930 in a monograph based on a large epidemic in Berne was convinced that monocytic angina was indistinguishable from glandular fever with membranous angina—both clinically and hematologically In 1932 Paul and Bunnell introduced the heterophile antibody test which has been found positive in a high percentage of cases This test which depends upon the presence of sheep cell agglutinins in the patient's serum has been made more specific by *Bailey and Raffel* and by Davidsohn through the use of absorption methods

Incidence—The disease occurs in sporadic and epidemic form most commonly in children and young adults It has been described in North America, South America and in most European countries as well as in Egypt Australia Japan and China In this country the most frequent variety is the sporadic type affecting young persons between the ages of fifteen and thirty Sporadic cases occur in children but are usually mild, and may therefore be over looked Numerous epidemics among children and in boys' schools have been reported but with one exception all of these were prior to the introduction of the serologic test for infectious mononucleosis While infection has been spread by contact from one *adult to another it is doubtful whether the* disease has ever assumed epidemic proportions among adults There were 10 per cent adults in one epidemic It is noteworthy that infectious mononucleosis is frequently recognized in medical students nurses, and hospital personnel where examination of the blood is a routine procedure in diagnosis Numerous cases in the general population are undoubtedly overlooked

Etiology—The causative agent of infectious mononucleosis is unknown The demonstration of the fusospirochetal group of organisms in a considerable percentage of cases with exudative throat lesions has not led to any convincing evidence of their etiologic importance though the pharyngeal exudate injected into guinea pigs has been shown to produce a similar blood picture Isolation of *Listerella monocytogenes* (Nyfeldt) from blood cultures of patients with the disease has been reported but lacks confirmation The most promising field of study that of the filtrable virus has not thus far yielded any conclusive results

Morbid Anatomy—Our knowledge of the pathology of this disease is limited to the study of glands removed at biopsy There is extreme hyperplasia of both lymphocytes

and reticulum at the height of the disease In some of the lymph nodes, collections of small lymphocytes are seen suggestive of early lymphatic leukemia but one does not encounter the complete obliteration of normal structure nor the invasion of the capsule which are found in fully developed cases of leukemia

Symptoms —After an incubation period of about a week and occasionally longer, the disease may begin either insidiously or rather acutely with a varying degree of fever sore throat and enlargement of the lymph nodes and spleen The symptoms occasionally may be so mild as to escape attention entirely or the disease may be rather severe Although the presenting symptoms encountered in some instances are most atypical and unusual (such as jaundice various skin rashes and signs of meningitis) the great majority of cases fall into one of two clinical groups The commonest form encountered in the United States is the *anginose* or *pharyngeal variety* This attacks young adults in a sporadic manner The onset is usually insidious and the initial complaints rather mild and indefinite such as sore throat headache fever sweats general malaise chilly sensations or slight swelling of the cervical glands By the end of a week the lymph nodes of the neck and often of the axilla and groin have definitely enlarged the throat shows a pharyngitis or tonsillitis with patches of exudate suggesting diphtheria but often containing the fusospirochetal group of organisms and the spleen has become palpable in about one half of the cases The liver is enlarged in about 10 per cent of cases The time of appearance of the sore throat and glandular enlargement is quite variable these features may occur early midway or late in the course of the disease For several days the fever may be high 103° to 104° F or even higher and the patient very uncomfortable but there is not the extreme constitutional reaction of severe diphtheria streptococcus infection or acute leukemia The glands do not suppurate Among the uncommon and confusing findings which may mask the actual identity of the disease are jaundice purpura a variety of skin rashes which may resemble measles scarlet fever or typhoid fever and meningismus or true meningitis with 600 or more cells per cubic millimeter mostly lymphocytes in the spinal fluid

The *glandular* or *Pfeiffer type* is most commonly seen in children in sporadic and epidemic forms It is rarely encountered beyond the twentieth year The presenting symptoms are slight sore throat enlargement of the cervical glands and fever In contrast to the anginose form examination of the throat reveals only slight redness but no exudate Axillary inguinal node, and splenic enlargement may or may not be present Involvement of the mediastinal glands may produce cough and enlargement of the retroperitoneal lymph glands may be responsible for abdominal pain nausea and vomiting simulating acute appendicitis Suppuration of the glands does not occur Hemorrhagic nephritis has been described in children as a rare complication After the glands on one side of the neck have markedly diminished in size and the temperature has fallen to normal a recrudescence may occur with rapid involvement of the other side Skin rashes are rare in this type of the disease Recovery usually occurs within a period of two to three weeks

Less frequently the two classical features of sore throat and glandular enlargement may remain in the background or be replaced by other presenting symptoms Thus Tidy emphasizes a febrile form resembling influenza or typhoid Angina is uncommon lymph node enlargement is late in developing and a maculopapular rash appears on the fourth to tenth day In still other instances purpura or a scarlatiniform eruption has been reported Since the introduction of the sheep cell agglutinin test our concept of infectious mononucleosis as a general systemic disease has widened Thus cases which formerly would have been diagnosed as serous meningitis (lymphocytic meningitis) and as catarrhal jaundice have been shown to have a marked increase in sheep cell agglutinins and later have developed glandular enlargement and a typical blood picture

Blood Picture —The red cells hemoglobin and platelets are normal The white blood cells vary in number and character with the stages of the disease During the first few days the total white count may be normal or subnormal with the percentage

of polynuclears normal or slightly increased After six to ten days there is a leukocytosis ranging from 10 000 to 20 000 or above with a decrease in polynuclears and 50 to 85 per cent of the large characteristic cells of the lymphocytic group The predominating cell is a lymphocyte, a varying number of which are abnormal showing deeply basophilic cytoplasm which often contains vacuoles Although there may be difficulty in clas sifying these cells when stained by Wright s method supravital preparations show the majority to be large lymphocytes usually with moderate increase in monocytes By the end of the third week the total white count falls and the percentage of lympho cytes decreases In the glandular form of the disease in children one may encounter an early leukocytosis and polynucleosis which later shifts to a lymphocytosis

Serologic Test —In approximately 90 per cent of cases of infectious mononucleosis the patient s serum contains heterophile antibodies in the form of agglutinins for sheep red blood corpuscles in a titer of 1 to 32 or higher (Paul and Bunnell) Agglu tinins are present in low titer during the first few days but by the second or third week average 1 to 256 or higher falling off sharply as a rule by the fifth week The serum of normal individuals may contain agglutinins in 1 to 8 dilution and patients who have received horse serum may show a titer of 1 to 64 or higher To exclude normal agglu tinins and those due to horse serum injec tions thus making the test more specific for infectious mononucleosis absorption tests with guinea pig kidney and ox cells have been introduced by Bailey and Raffel and by Davidsohn At present there are a cer tain number of seronegative cases in almost every large series reported but further study with the differential absorption test will be necessary before one can definitely state the exact percentage of positive reactions Sero negative cases are believed by some authors to occur more frequently in sporadic cases among children The Wassermann test may be temporarily positive in 6 to 40 per cent the incidence being greater late in the dis ease It tends to return to normal as the heterophile antibody decreases in amount

Prognosis —This is uniformly favorable and the patient is usually well in three to four weeks In some the glands may re main enlarged for several months the lym phocyte percentage or the type of cell may be abnormal and the patient may feel below par for a long time—as long as five or six months

Diagnosis —The diagnosis may be rela tively easy or difficult The sheep cell ag glutinin test and the differential blood count are of the greatest value in differential diag nosis of a disease with such protean mani festations One must remember that infec tious mononucleosis may masquerade under many different guises Its true nature can be recognized by applying the two labora tory procedures above mentioned Confusion may occur with (1) Vincent s angina diph theria or tonsillitis (sore throat), (2) tuber culous adenitis Hodgkin s disease syphilis and mumps (enlarged glands or spleen) (3) influenza typhoid undulant fever scar let fever measles and erythema nodosum or multiforme (fever and skin rash) (4) cat arrhal jaundice acute appendicitis and lym phocytic meningitis (abdominal or menin geal symptoms) and (5) acute lymphatic leukemia granulocytopenia and thrombo cytopenic purpura (blood dyscrasias)

Treatment —Rest in bed is indicated dur ing the febrile period The diet should be that suitable for a mild infection Should the throat lesions show large numbers of Vin cent s organisms a strong oxidizing gargle such as perborate should be used and local applications of 5 per cent neoarsphenamine in glycerin should be made The *sulfonamide drugs* are it appears of value only in case of a complicating hemolytic streptococcus infection Berkley has recently reported complete clinical recoveries within forty eight hours in a small series of cases follow ing the administration of 100 cc of scarlet fever convalescent serum intravenously Further confirmatory studies must be made before final judgment is passed on this type of therapy

MILK SICKNESS

(*Trembles*)

Milk sickness better known as the trembles is an afebrile disease due to the ingestion of milk milk products or the flesh of animals suffering from the disease

History.—Nicolay and Hay in their "History of Abraham Lincoln" claim that Nancy Hanks the mother of Lincoln died of milk sickness "In the autumn of 1818 the little community of Pigeon Creek was almost exterminated by a frightful pestilence called the milk-sickness " Nancy Hanks was one of the victims

Incidence—At the present time milk sickness is a rare disease but a century ago the condition was common in various parts of the United States It was quite prevalent throughout the Mississippi Valley particularly in Ohio Indiana Illinois and Michigan There is no record of milk sickness having ever occurred outside the United States

Etiology—Although there is some doubt as to the etiology of the disease the evidence seems to be fairly conclusive that milk sickness is caused in the majority of cases by a plant known as white snakeroot *Eupatorium urticaefolium* In New Mexico and Arizona this plant has not been observed but what is apparently the same disease also occurs in these states and is due to another herb the rayless goldenrod *Aplopappus heterophyllus* which probably contains the same toxic agent found in white snakeroot In man the disease results from eating butter or drinking the milk from cattle which have ingested the weed It is also possible for the human being to be poisoned by the beef of cattle that have eaten of this plant When extract of white snakeroot is fed to laboratory animals they become ill refuse food and develop a generalized tremor Couch who was one of the first to isolate a toxin from white snakeroot named it *trematol* which according to Couch exists in the plant partly in ester combination with a resinous acid

Symptoms—Milk sickness is characterized by a gradual onset of weakness loss of appetite and vomiting These early symptoms are followed by constipation and abdominal distress There is no fever but marked thirst is usually noted The mind is clear but in fatal cases coma may precede death by several hours The average duration of the disease is seven to nine days although symptoms may continue much longer

Prognosis—The prognosis is grave in both acute and subacute cases Moseley states that the death rate is about 25 per cent

Treatment—The treatment is purely symptomatic Prophylaxis consists of avoiding meat and milk products of animals with trembles and in pasturing cattle on cleared or plowed land

MILIARY FEVER

Definition—Miliary fever is an acute infectious disease which occurs in epidemic form and is characterized by abrupt onset of fever excessive sweating prostration and erythematous rash

Incidence—Most of the epidemics have occurred in Europe and the sweating sickness which swept over England during the 15th and 16th centuries was probably miliary fever An epidemic occurred in France in 1907 Zeiss made an epidemiologic study of the disease in Russia in 1932 So far as is

known, the disease has never occurred in the United States

Etiology—The cause of miliary fever is not known nor is its mode of transmission understood The epidemics which have been studied have occurred most frequently in the spring and summer months Individuals of all ages are susceptible The mode of spread is rapid, in this respect resembling that of epidemic influenza

Symptoms—The most striking feature of miliary fever is the profuse perspiration It begins with the onset of fever which continues throughout the course of the disease The eruption which appears on the third or fourth day is usually of the papulovesicular type occurring first on the neck back and chest and later in the axillae and between the thighs Occasionally a purpuric form of the disease with other manifestations of hemorrhage is noted As the rash appears there is gradual diminution in the intensity of the symptoms and after two or three days desquamation occurs Convalescence is characterized by weakness loss of weight and slow recovery

Prognosis—The prognosis is usually favorable but occasionally the patient develops a high fever, dyspnea and rapid pulse followed by delirium and death

Treatment—Treatment is symptomatic

AINHUM

Definition—Ainhum is a chronic disease of unknown cause usually affecting the little toe and characterized by the formation of a furrow at the digitoplantar fold which deepens and extends until the toe is encircled and eventually separated from the foot

Incidence—Ainhum has been observed chiefly on the west coast of Africa and in Brazil Cases have been reported also from the West Indies and rarely from the southern portion of the United States Apparently white people are not susceptible, all the cases reported have been observed in the black race There is some evidence that ainhum is a familial disease, as it may occur in several members of the same family or in repeated generations of the same family It occurs chiefly in male adults between twenty five and thirty years of age

Etiology—There have been various theories as to etiology Some have claimed that it was related to leprosy This seems however most unlikely, it is much more probable that the disease is a trophoneurosis secondary to some local trauma Castellani believes that the infection is parasitic in origin and that infection takes place through small superficial lesions or wounds often found on the feet of people who do not wear shoes

Morbid Anatomy—In a typical case a fibrous cord replaces the bony structures normally attaching the bone to the foot The skin becomes thickened and the walls of the blood vessels show an endarteritis with a secondary rarefying osteitis

Symptoms—According to Still the little toe is the one affected in 90 per cent of the cases more rarely, the fourth toe and very rarely both the fourth and the little toe are implicated Both little toes may be attacked at the same time, but the condition usually starts in one toe The initial appearance is featured by a crack in the digitoplantar fold of the little toe This extends laterally and finally appears on the dorsum of the toe The distal portion of the toe enlarges and becomes bulbous In the final stages the connection between the foot and the little toe is a slender fibrous cord which permits the toe to wobble in various directions and to interfere greatly with walking

The course of the disease extends over several years if the toe does not undergo spontaneous amputation as a result of injury to the pedicle The disease is practically painless

Treatment—Ainhum is best treated in the early stages by longitudinal incision into the grooved furrow In the later stages amputation is usually necessary

DISEASES OF ALLERGY

INTRODUCTION

Clinical conditions such as asthma hay fever urticaria, serum disease serum shock, angioneurotic edema eczema and many others involving skin brain (or its membranes) and intestinal tract have gradually come to be recognized and grouped as diseases of allergy The development of a concept in explanation of disease is often as instructive a story as its application Certainly this holds true for the field of allergy today where our knowledge is still vague and far from complete

Although allergy as an explanation of certain human ills dates back only to early years of the present century, the foundations were laid in observations recorded throughout medical literature from its earliest years The physical eccentricity of occasional persons to certain foods was perhaps appreciated by Hippocrates and prompted him to write in his sixty fourth aphorism It is a bad thing to give milk to persons having headache But the major part of the early history consists of records of unusual responses of rare persons to commonly prescribed drugs Such effects having nothing in common with the pharmacologic action were quite properly classified as idiosyncrasies without attempt at explanation or hypothesis

Our present-day knowledge of allergy is really an accidental by product of the general use of diphtheria antitoxic serum which was discovered by von Behring in 1890 Three effects following injection and due to the serum not its antitoxin were soon observed Occasionally it produced a prompt violent reaction (serum shock) that was often fatal Again many persons developed a generalized urticaria in ten to fourteen days (serum disease) and lastly it produced an artificial sensitiveness (anaphylaxis)

This latter result was reported by Theobald Smith in 1904 While working with antitoxin he observed that many of his experimental animals died immediately upon receipt of the second injection when a sufficient interval of time had elapsed after the first one This came to be regarded as essentially identical with the increased sensitiveness to toxins which Richet had reported as anaphylaxis in 1898 hence this term was applied to the Theobald Smith phenomenon Anaphylaxis took the medical world by storm Soon practically every research laboratory gave time to its study on experimental animals Finally out of the mass of conflicting data and theories we emerged with a fairly definite knowledge of the fact of an artificially induced and specific ' sensitization of tissue cells with the serum acting as the reservoir for the excess antibody produced But even today we have no definite knowledge of why certain cells respond with antibody production to parenterally introduced antigens nor of just what antibody is nor of any of the intimate details of the explosive reaction we call anaphylactic shock These problems are receiving attention and their solution will constitute another milestone for biologic science

Naturally anaphylaxis was not long neglected by the clinicians Wolff Eisner suggested it in 1906 as an explanation for hay fever It was known that pollen was the cause—Blackley had proved this in 1873 He recorded the first skin and eye tests using pollens and witnessed local and general reactions not obtainable in persons not suffering from hay fever In 1909 Gillette collected the scattered records of cases of sudden death following diphtheria antitoxin injections This too was regarded as anaphylaxis He first called attention to the similarity of symptoms to those of asthma but noted the important fact that serum shock had in most cases followed the first injection Thus asthma was brought into the field as well as urticaria which was a common accompaniment of the dyspnea and was also the chief symptom of serum disease It then seemed simple Hay fever asthma and urticaria were the human manifestations of anaphylaxis That this is not strictly so

will be evident from later discussion but this was the starting point for the development of the hypothesis of sensitization as the explanation for the group which we now call diseases of allergy

This word meaning altered reactivity was coined by von Pirquet in 1906 to indicate certain changes of reaction induced by first injections and not related at all to immunity conferred This opinion was voiced by von Pirquet not only as a result of his own observations on altered reactions to a second and subsequent injection of smallpox vaccine and horse serum, but also to the already recorded findings of similar changes caused by other antigens noted by Richet von Behring Wolff Eisner and others Today largely because it is conveniently short and euphonious allergy has been adopted by common consent to denote the sensitization reaction of man hence it either includes or is synonymous with hypersensitiveness sensitization idiosyncrasy anaphylaxis and atopy

The grouping under allergy of such an array of seemingly unrelated and dissimilar conditions as hay fever urticaria asthma eczema finds a basis in *clinical association* and *immunologic relationship* (1) The *clinical association* was well demonstrated in a study of 621 cases of asthma and hay fever by Cooke and Vander Veer in 1916 They showed that a large percentage of the cases had past or present histories of urticaria eczema angioneurotic edema and various other curious and unusual food and drug reactions and they further established that these same conditions were common among antecedents collaterals and descendants In other words allergies were manifestations of a familial trait (2) The *immunologic relationship* rests upon the concept of sensitization to explain all the unusual and abnormal reactions of cells to the presence of substances which under usual conditions in normal persons produce no obvious reaction whatsoever

We may define the allergic state as one of potential specific reactivity due to the existence in certain cells of a mechanism (antibody) which mediates the linkage of the cell to the specific substances (antigen)

Allergy is the resulting reaction qualitatively altered from the normal of the species when union of antigen with sensitized cell is effected This broad definition regards as allergy all specifically mediated reactions hence criticism may be made as it would include the reactions resulting from the transfusion of an incompatible human blood in man It is true that the word 'allergy is not yet used for this purpose but because this special antibody is normal physiologic spontaneous and hereditary is certainly no argument as we shall see against the inclusion of such lytic and agglutinative reactions as allergies

It must be understood that allergy is not a single or uniform biologic phenomenon There are different pathogenic etiologic pathologic and immunologic as well as clinical varieties We shall consider these in order

Pathogenesis —*Induced Physiologic or Normal Allergy* —1 Injection of small amounts of horse serum as diphtheria antitoxin produced serum sickness in about 10 per cent of all cases With the use of large doses of pneumococcus antiserum the incidence rose to 90 per cent That individuals after serum disease remain allergic for some time can be proved by the positive skin reaction to a test dose of serum and by the serum changes later discussed

2 A dermatitis often results from contact with certain dyes and vegetable oils Studies with the oils of ivy and primula have been most illuminating Without details we may sum up by saying that newborn babes and adult Esquimaux do not develop dermatitis with the first application of these oils Following Low s studies with primula Straus found that the second application of ivy oil to the infant s skin two to four weeks after the first gave an eruption in 73 per cent of those retested Obviously the skin eruption is not due to any toxic or irritative quality of the oil but is explained as a sensitization developed as a result of an earlier contact

3 Not infrequently infection with a particular type of bacterium produces a state of reactivity to that organism or its products A reaction to tuberculin is well recognized to exist in practically all cases infected with the tubercle bacillus There is no reaction to the test in the uninfected

Here are three typical examples of clinically different reactions which are explained

by allergy since the primary action of the antigen is neither toxic nor irritative One sensitization results from contact with serum another from ivy oil and the third follows tuberculous infection Since they are or may be specifically induced at will by proper contact and since the great majority of the species react alike in each instance I have grouped them under the general head ing of Induced Physiologic or Normal Allergy

Spontaneous Pathologic or Hereditary Allergy—The important group of clinical allergies—asthma hay fever eczema angio neurotic edema etc—forms a striking con trast to the induced allergies They occur in but a small proportion something under 10 per cent of the population they have never yet been artificially produced by any sort of contact they seem to appear spon taneously and paternal as well as maternal heredity has been proved to be an impor tant predisposing factor The cause of the development of sensitization is not so read ily explained in these diseases Studies have shown that skin sensitizing antibodies can not be transmitted through the placenta to produce passive sensitization of the fetus One school believes today that they are analogous to experimental anaphylaxis that is induced by contact stimulation A point in favor of this idea is that allergies in infants are frequently due to foods The sensitization to substances not included in an infant s diet may be assumed to be the result of contact during intrauterine life Then too there are certain serologic simi larities to be discussed later

But this concept does not explain the many vagaries of the sensitization of man It does not take account of the part that heredity has been shown to play nor of the fact that many of the antigenic (reacting) substances are nonprotein nor of the fact that the commonest allergens are substances with which there is relatively little contact On the other hand to prove the entire ab sence of contact prior to the sensitization is impossible

Following the thought suggested by Burky s work with staphylococcus toxin and in line with Bailey s findings of hemol ysin in serum of rabbits infected with Bacil lus lepisepticus together with the clinical observation that many allergies follow in the wake of acute infections it may be that bac terial products or toxins act synergistically to enhance the antigenic property of a sub stance that happens to be at hand at just the proper moment It may even be that the real antigen is not the particular substance as we know it egg albumin or pollen protein or quinine but is rather some derivative of these substances with a special molecular configuration After all allergic reactions are fundamentally chemical or physiochemical rather than biologic hence the mechanism may be initiated by one molecular structure with a resulting sensitization to chemically related structures occurring in biologically unrelated fields

But there still is the possibility that this type of allergy is spontaneous The thesis has not been disproved and support for it is found in the lysins and agglutinins which normally appear in the various blood groups They are determined solely by heredity and not by contact stimulation However it must be admitted that we do not yet know how the sensitization starts what deter mines the allergen or the clinical form of the allergy for the particular case From among our many contacts why one becomes reac tive to pollen another to food while a third develops allergic symptoms from infection is not explained by the mere assumption of contact and general hereditary susceptibil ity This type of allergy is further distin guished by the extreme degree of reactivity by the multiplicity and variety of the sen sitizations and their long continuation even in the complete absence of contact At pres ent we must say that contact may or may not be necessary to set off the allergic mech anism in man If it is then a very mild one only may be needed to initiate a variable highly reactive and self perpetuating allergy to one or more substances that seem to be predetermined by nature or heredity as other contacts great and small are ineffec tive

Etiology.—The exciting causes of an allergic reaction in man that is the antigens are many and varied They may be absorbed by ingestion inhalation injection from a focus of infection or from external contacts The list contains the pollens danders and many other air borne substances of animal

and vegetable origin foods drugs, therapeutic sera and bacteria and their products Sensitization is not limited to proteins though they are the commonest antigens, but it is known to exist to fats, oils, resins, metals, and to such simple organic compounds as the alkaloids and benzol ring derivatives

Pathology —It is obvious from what has been said that allergic reactions show several different types of cellular reactions thus exhibiting a varying functional or organic lesion

The simplest pathology is the functional *edema* and *hyperemia* occurring singly but as a rule together This lesion is illustrated in the urticarial wheal and in vasomotor rhinitis

The inflammatory organic lesions of allergy may be *exudative* as in eczema and related dermatoses *productive* as in hyperplastic rhinitis and sinusitis and periarteritis nodosa In some cases *necrosis* and *ulceration* occur as in certain drug allergies lupus erythematosus and others

Hemorrhagic lesions also occur The purpuras of the nonthrombocytopenic and symptomatic groups are allergic

In general the histology varies depending upon the tissue involved the type of allergy and the nature of the antigen A detailed discussion is not required We only wish to indicate the varied histologic picture

Immunology —(1) Experimental anaphylaxis (2) serum disease in man and (3) asthma from contact with horses or on administration of horse serum are regarded by some immunologists as identical because of certain identical features and by others as essentially different because of important differences

(1) In the animal foreign protein injections produce cellular and serologic changes which are spoken of as anaphylactic Reinjection of the protein at the proper time produces shock and death immediately The sensitization can be transferred to another animal by the serum The serum demonstrably contains three immunologic antibodies (*a*) precipitins shown by suitable test (*b*) muscle sensitizing bodies shown by the response of the uterine strip (Dale reaction), and (*c*) skin sensitizing bodies first demonstrated by Cooke and Spain Using the Prausnitz Kustner technic a small amount of the sensitive serum was put into the superficial layer of skin of a normal man When later tested with the specific serum this site gave an immediate urticarial wheal whereas other portions of skin did not react This serum transfer of skin sensitiveness from sensitized animal to man is not so regular a finding as is the precipitin or the Dale reaction but it is definite and has been confirmed by de Besche and others

(2) In man injected with sufficient serum sensitization develops in roughly ten days at which time a generalized urticarial eruption appears (serum disease) In this serum are found the same three antibodies as in the animal—the man has been artificially sensitized and remains so for some time thereafter In other words, serum disease is but an incident in the development of the sensitization He is then anaphylactic as is the animal but not asthmatically allergic to horse contact It is probable he would die in shock if injected at the proper time There are of course no definite experiments but clinical reports sustain the idea This artificially sensitized man loses his reactivity in time measured by weeks

(3) The human being who has developed asthma and reacts on skin test with the serum frequently has no history of contact with horses or often a very slight one He is the person who reacts violently immediately often fatally if injected with serum Serologic studies in these cases have shown neither precipitins nor smooth muscle sensitizing bodies but the serum does contain the transferable skin sensitizing antibodies These patients never purposely sensitized develop a degree of allergy infinitely greater than that ever produced artificially by large amounts of injected serum and they possess a sensitization that once begun usually lasts a lifetime even without specific contact The literature does not appear to contain any reports of attempts to desensitize the artificially sensitized nonasthmatic man Theoretically it should be possible It has been attempted but not successfully with the naturally sensitized asthmatic

The only point of identity then between the man who has been artificially sensitized and the so called spontaneously sensitized

asthmatic is that both are specifically reactive by the skin test, giving an immediate urticarial wheal and the sera of both transfer this reactivity to normal human skin It is upon this slender evidence that identity is claimed for the induced physiologic anaphylaxis and spontaneous or hereditary asthma

There is no knowledge of the immunology of induced allergies represented by the tuberculin reaction and dermatitis venenata In the absence of any serum antibody demonstrable by the passive transfer test we assume the existence of a cellular antibody to mediate the abnormal response to substances which are not in themselves reactive

Immunologic Types of Clinical Allergies —In spontaneous or hereditary allergy clinical observation indicates two immunologic types that may be differentiated depending upon whether the symptomatic reaction occurs *immediately* (within an hour) upon contact or whether it is *delayed* Let us see what important differences are found

(*A*) The Immediate Type —A patient states that contact with horses will give asthma and hay fever within a very few minutes When tested with the dander extract in the skin an immediate wheal with itch and erythema develops in a few minutes A drop of the extract in the eye produces erythema itching and tearing just as quickly If the extracts of dander dust pollen or food give an immediate skin test reaction then clinical contact with that substance will in general produce the prompt clinical reaction A clinical story then of a general or systemic reaction following immediately (one hour) upon a contact whether inhaled or ingested will in general be substantiated by an immediately positive skin test with that substance In the serum of these patients the presence of the skin sensitizing antibodies is demonstrable by passive transfer to normal skin The scratch or intradermal skin tests are valuable in diagnosis in this immunologic group and in this group alone This is the general rule There are exceptions

(1) Positive skin tests do not always signify clinical sensitiveness This is illustrated by a patient found positive to skin test and negative to eye test with ragweed extract with no clinical history of hay fever Immediately after a small injection of ragweed extract the patient gave a general reaction with urticaria cough sneezing and watery eyes The test indicated his allergic state but he did not have clinical hay fever (2) Negative skin tests do not always mean absence of immediate clinical reaction As a rule the so called ' nonantigenic substances like aspirin and quinine etc do not give positive skin tests when they produce an immediate general reaction of asthma without urticaria My records show only one case of an immediate aspirin reaction with asthma and urticaria and here the skin test was positive Also in my records there is but one case giving an immediate asthmatic test reaction without urticaria to fish protein and here again the skin test was itself negative The subject was similarly sensitive to aspirin Such cases are great rarities

(*B*) The Delayed Type —A clinical allergic reaction perhaps an urticaria or an edema or even an asthma may begin not immediately, but anywhere from several hours to several days after contact with a particular substance In such instances not only does the reaction always occur but it occurs after essentially the same incubation period Frequent recurrences of the reaction do not serve materially to shorten or lengthen that time interval although the severity of symptoms may increase In such cases the skin test with the substance proved by clinical test to be the cause is uniformly negative even when the clinical reaction is urticaria The passive transfer test is also negative Obviously we are dealing with a mechanism of reaction which is immunologically different from the *immediate* type This we call *delayed* allergy Its mechanism is unknown while the fact of its existence is clear It resembles serum disease only in its incubation period and perhaps in the rash It differs however in having none of the serologic findings and no positive skin test at any time In this group we see reactions to foods drugs and bacterial substances but very rarely to air borne substances Many of the cases of urticaria and angioneurotic edema both external (cutaneous) and internal (abdominal and cerebral) of eczema and other dermatoses belong in this group also all allergies of infective origin producing

bronchial (asthma), nasal and skin symptoms

Certain lesions of infectious disease are today attributed to allergy as for example the rash of scarlet fever the joint manifestations of certain arthritides and the inflammatory and necrotic lesions of tuberculosis to mention but a few Some of them belong in the group of physiologically induced allergies as they are the usual and normal response of mankind but others belong in the pathologic group in which like asthma hereditary influences are important Whether or not the mechanism of the allergy in the two groups is identical is not known today

Clinical Types—There seems to be no part of the body—no organ no tissue cell—that may not be sensitized and respond with one or another of the several pathologic or immunologic types of reaction we have discussed but the tissues derived from the ectoderm, skin, mucous membrane, and nervous system are most commonly involved Hence we have in the skin such allergic lesions as urticaria purpura eczema contact dermatitis, lupus erythematosus dermatitis herpetiformis and others In the nose vasomotor and hyperplastic rhinitis and sinusitis are the usual manifestations In the abdomen an allergy may be manifested by simple indigestion acute and chronic gastro enteritis and colitis or it may simulate an acute condition within the abdomen requiring surgery Cerebral allergies are also recognized giving rise to migrainous and epileptiform attacks paralysis and coma as well as symptoms of multiple sclerosis and encephalitis

Diagnosis—A history of allergy in direct or collateral antecedents or in the sibs or descendants or a well defined allergy such as hay fever in the personal history makes for a presumptive diagnosis of allergy in a patient with obscure long standing persistent or recurring symptoms Especially is this true when such symptoms are referable to lesions in tissue of ectodermal origin

The skin test for allergy should seek to reproduce the histologic picture of the clinical allergy under study for example one cannot and should not expect to make a diagnosis of the cause of eczema which is an exudative and delayed allergy by means of the intradermal test which can only indicate the edematous immediate type of reaction Disregard for this fundamental principle has led to great confusion and error

The skin tests are important diagnostic aids but only when properly interpreted and only in that immunologic type of allergy we have described as 'immediate' Other special diagnostic measures of value are the environmental tests and restrictive diets which will not be discussed in detail here

Prognosis—Most of the important clinical allergies are of the type we have described as spontaneous or hereditary Thus they represent an ingrained constitutional defect Such individuals are likely to have not only recurrences but different clinical varieties of allergy reappearing at any time through life It should be appreciated that while we may control the evidence of allergy by avoidance of the exciting agent or injection against it we do not cure the sensitization nor prevent its reappearance in some other form to some other allergen

HAY FEVER

(Allergic Coryza Vasomotor Rhinitis)

Introduction—Nasal allergy or allergic coryza manifests itself in different clinical types according to the nature of the substance producing the reaction The immunologic mechanism of the vasomotor reaction

is that of the immediate type of allergy in which positive skin test and passive transfer reactions are obtained When the clinical reaction is due to pollens it is termed seasonal coryza' When a similar condition exists continually or intermittently throughout the year depending entirely upon contact with the allergen it is called perennial coryza

ROBERT A COOKE

SEASONAL HAY FEVER

(*Rose Cold Pollinosis*)

History —The following facts stand out as important in the development of our present conception of the nature the causative factors and the treatment of hay fever Bostock in 1819 identified the seasonal coryza as a clinical entity Elliotson in 1831 suggested the pollens as causative factors In 1873 Blakeley a hay fever victim used extracts of pollens upon himself and was able to precipitate an attack Dunbar conceiving that the pollen contained a toxic albumin attempted to immunize horses against the toxin He believed that the serum of injected horses contained a specific antitoxin and this immune horse serum was used in treatment and sold under the trade name of Pollantin This serum not now in use, was never shown to contain a specific pollen antibody Wolff Eisner in 1906 suggested that hay fever was a specific anaphylactic reaction Freeman and Noon in 1911 were the first to publish results on the treatment of hay fever by active immunization with pollen extracts Clowes in 1913 reported on the specific reactions exhibited by hay fever cases Cooke in 1915 reported on 144 cases treated by injection with extracts of pollen Since this time a considerable amount of work has been done the important pollens have been determined and the technic of diagnosis and the method of treatment have been fairly well systematized

Etiology —The air borne pollens are the important etiologic factors but almost any pollen may cause hay fever when it is presented in sufficient concentration For the eastern part of the United States it is possible to distinguish 3 seasonal varieties of hay fever The *spring type* begins at the end of March or early April and extends to the end of May This is due to the pollens of trees especially the oak elm birch hickory ash and poplar The *summer type* beginning at the end of May and extending to the middle of July is caused by the pollens of grasses plantain and sorrel The *fall type* begins in the middle of August and continues until frost The pollens of the ragweeds are mainly responsible for this type In the southwestern states the amaranths artemisias and mountain cedar are also factors For detailed information monographs must be consulted In 1928 Parlato showed that the dust of the caddis fly also caused typical hay fever

As a predisposing factor in pathogenesis heredity is important

Incidence —Accurate statistics are not available Hay fever usually begins between the tenth and thirtieth years Both sexes are equally liable

Morbid Physiology —In 1919 Ramirez reported what appeared to be a passive transfer of hypersensitiveness by means of blood transfusion The donor had clinical symptoms of coryza and asthma on exposure to horses Following transfusion the recipient developed an attack of asthma after exposure to a horse He had never had asthma before In 1921 Prausnitz and Küstner demonstrated that the serum of a fish sensitive patient when injected intradermally into a normal man produced a localized skin sensitiveness The injected site reacted to the fish preparation whereas the other areas of skin in the normal man showed no response This phenomenon known as passive transfer of sensitiveness was confirmed by de Besche It is now generally accepted that the blood serum of certain clinically sensitive cases contains antibody which specifically sensitizes skin cells to the allergen to which the donor is sensitive This is the type of allergy met with in most of the seasonal and perennial hay fever cases

The earliest observations on cases of human allergy have shown that the immediate reaction can be demonstrated in the skin as well as in the mucous membranes of individuals with clinical hay fever and asthma This general skin sensitiveness is made use of in diagnosis The functional change in nasal membranes in hay fever is purely vasomotor

Morbid Anatomy —There is no organic pathology in uncomplicated seasonal coryza The bony and cartilaginous structure and the mucous membrane of the nose may be as normal in appearance in patients with hay fever during the free period as they are in the normal man Organic lesions such as suppurative sinusitis polyposis and hyperplastic rhinitis and sinusitis are the result of infection of the nasal membranes and are not uncommon

Symptoms.—The symptoms of hay fever are essentially local and due to the reaction at the point of contact in the mucous membranes of the eye, nose and pharynx They vary considerably in severity In occasional cases peculiar variations have been noted such as those in which the symptoms are entirely nasal and there is no clinical ophthalmic reaction Or more rarely one eye only is involved or one eye is much more sensitive than the other During the attack the symptoms vary greatly in severity from day to day or from hour to hour They consist of an *itching* and *congestion* sometimes even of an edema of the mucous membrane of the sclera and conjunctiva *Photophobia* of greater or less degree results There is itching of the nose and sometimes of the skin over the nose and the face *Sneezing* occurs in paroxysms is violent and is accompanied by a thin alkaline, irritating mucous discharge Congestion and edema of the mucous membrane of the nose occur and when the edema is great there may be complete obstruction to nasal breathing Itching is often felt in the ears on the roof of the mouth and in the pharynx

The clinical picture of seasonal hay fever is quite typical It is particularly characterized by its strictly seasonal occurrence and by the fact that in any given patient the attack from year to year begins and ends on approximately the same date This is quite readily explained by the fact that in any given locality the pollination of plants is very little influenced by weather variations

Complications.—*Multiple Reactions*.—Over 50 per cent of hay fever patients are hypersensitive to more than one allergen Approximately 33 per cent of those with the summer type of hay fever are clinically sensitive also to the pollen of ragweed and it is not uncommon for seasonal hay fever to begin in the spring and continue until frost The essential point is that attacks do not occur during the winter months Seasonal hay fever is not infrequently combined with the perennial type In this case there is a perennial disturbance, with exacerbations occurring in the pollen season These complex manifestations can be recognized only by means of the diagnostic tests Occasionally typical seasonal hay fever the fall type for example does not cease at the time of frost but continues into the winter This may be the result of an additional reaction or a secondary sinus infection

Infection.—Infections of the paranasal sinuses occur in a large percentage of cases but in only a *relatively small* percentage does this infection become clinically important and warrant *special treatment*

Asthma.—Asthma may be caused by the *allergic reaction to the* pollen In such cases it begins one or two weeks after the onset of hay fever but *terminates with it* This type occurs in about 30 per cent of all cases of hay fever There is also a type of asthma which results from infection of the paranasal sinuses This form usually develops late in the course of hay fever and may persist long after the seasonal limits of hay fever

Diagnosis.—We shall limit discussion to the diagnosis of causative factors An important index of probable causes of hay fever is obtained by an accurate history of the time of onset and offset of the attack One should also bear in mind that multiple sensitizations are present in about half of the cases so it is wise to test also with the more important substances that are factors in perennial hay fever (See Nonseasonal Hay Fever) If a reaction is obtained to one of the grasses the reactions to pollens of all other grasses will be about the same degree We believe these pollens are biologically identical If a patient reacts to one of the varieties of ragweed a similar reaction is always obtained with the others The same cannot be said however for the pollens of trees No uniformity of reaction has been found here except with species of the same genus For this reason all of the more important tree pollens must be tested if the patient s history indicates sensitiveness to this group

The diagnosis of the specific pollens to which a person may be sensitive is made by means of cutaneous and ophthalmic tests

Cutaneous Test.—The cutaneous test may be performed in two ways In the *scarification method* the desiccated or fluid extract of pollen or the pollen itself is applied to a small scarified area of the skin In the *intradermal method* the extract of pollen is introduced into the most superficial layer of the skin through a fine hypodermic needle

(26 gauge) The amount injected in any one test is about $\frac{1}{50}$ to $\frac{1}{100}$ cc This forms a small papule from 2 to 3 mm in diameter Using either method, from 6 to 8 tests may be made at one time The intradermal *method is the more delicate* and accurate of the two but in inexperienced hands the *scarification method is perhaps safer*

Tests are negative when there is no increase in the size of the original papule no zone of hyperemia and no itching Positive reactions are designated as "marked," moderate' or 'slight In the *marked reaction* from five to fifteen minutes after the introduction of the extract there develops an urticarial wheal with irregular outline and pseudopod projections extending out into a zone of hyperemia This wheal may become several inches in diameter if the reaction is very marked When the wheal exceeds 1 inch in diameter the subject is exquisitely sensitive to the extract in the concentration used and a general or constitutional reaction may result Itching practically always accompanies these reactions The wheal usually fades within two to four hours and becomes blended with the surrounding zone of hyperemia which may last from six to twenty four hours Occasionally even at the end of thirty six hours there is still hyperemia and edema at the site of the test *Moderately positive* reactions are merely less severe than the marked reactions There is a decided increase in the size of the papule without the marginal irregularity or pseudopod formation characteristic of the marked reaction There is a zone of hyperemia and itching Such reactions usually fade within two to four hours A *slight reaction* is indicated by very little increase in the size of the original papule There is a small zone of hyperemia and itching may or may not be present Such manifestations fade in one to two hours

Absolute reliance cannot be placed upon the positive skin test in diagnosis A positive reaction that can be verified at will is pathognomonic only of cutaneous allergy it does not always connote clinical allergy

Ophthalmic Test—A drop of the pollen extract used for the skin test is instilled into the conjunctival sac When the *test is negative* there is no change A *positive reaction* is indicated by itching of the eye lacrimation and congestion of the scleral and conjunctival mucous membranes In some cases the pollen extract is carried through the nasal duct and causes a nasal reaction with sneezing itching and serous discharge A positive ophthalmic test is practically pathognomonic of clinical sensitiveness and indicates that whenever the patient comes sufficiently in contact with this allergen under natural conditions a mucous membrane reaction is bound to ensue The ophthalmic test suffers from the fact that only a limited number of tests can be made and that it cannot be employed during an attack

As to the relative value of the cutaneous and ophthalmic tests we may say that they are to be regarded as complementary Practically one depends upon the skin test for reactions which in case of doubt may be verified by the eye test The cutaneous test indicates more accurately the degree of somatic reactivity and is used for the titration of sensitiveness which is so essential to proper therapy

Pollen Preparations—Of the many methods of preparing pollen extracts the most satisfactory is that in which the extract used for the therapeutic injections is identical with the one used for the cutaneous and ophthalmic tests The pollen allergens have been shown to be protein therefore the most satisfactory method of standardization of pollen extracts is by their protein nitrogen content. Protein nitrogen 0 000001 mg has been designated as one pollen unit using the technique of Cooke and Stull No method of standardization is entirely accurate for biological activity lessens in aging solutions out of proportion to determinable chemical change As this deterioration is due partly at least to enzymatic activity care must be exercised in keeping the extracts cold during preparation and throughout the period of use Of course care in the collection and storage of pollen for future use is equally important When proper attention is paid to these details the extracts are entirely satisfactory for about one year

Recent work has shown that there are at least three different proteins in ragweed pollen fraction #1 so-called has the chemical properties of a plant albumin fraction #2 resembles a plant proteose and fraction #3 which is alkali soluble has the qualities of a plant glutelin Ragweed sensitive patients do not all react alike to these fractions One patient may be more sensitive to one fraction and the next to another fraction Fraction 1 appears to be more active and important and is highly antigenic Fraction 2 seems to be largely responsible for the constitutional reactions in those patients that take pollen injections with difficulty as this *fraction is a poor antigen yet highly reactive in certain persons*

Titration of Sensitivity—It is necessary to determine not only the reacting pollens but also the patient's degree of sensitiveness which varies markedly This is important for the more sensitive cases cannot take the therapeutic doses required for the less sensitive This

titration of sensitivity is carried out by means of the usual test solutions of different strengths

Three test solutions containing 10 100 and 1000 units per cubic centimeter respectively are convenient for this purpose The *very sensitive* cases (*A*) give marked skin reaction to a test dose of 10 units per cubic centimeter and a marked plus wheal (2.5 cm in diameter) to the solution of 100 units per cubic centimeter *Moderately sensitive* cases (*B*) give marked reaction with 100 units per cubic centimeter and a marked plus *reaction with 1000 units per cubic centimeter* *Relatively insensitive* cases (*C*) give marked reaction with 1000 units per cubic centimeter

This grouping of cases must be regarded as only approximate but it has a very definite practical value in dosage

Treatment —*Climatic* —There is no particular locality in which the patient suffering from the *spring* or *summer type* of hay fever may be assured of complete relief except upon the ocean Patients suffering with the *autumnal type* may avoid the attack in the White Mountains on the coast of Maine, in California and Europe As a matter of fact pollen free air is all that is required for comfort This may be accomplished by air conditioning a room by simple filtration or dehydration Many practical machines are now on the market

Drug Therapy —Cocaine of course temporarily modifies the attack but except in case of the utmost severity its use is not warranted Epinephrine and ephedrine in the form of nasal sprays may help but are often irritative and produce a secondary reaction that is worse than the original condition Atropine sulfate ($\frac{1}{100}$–$\frac{1}{150}$ grain) lessens the discharge but does not relieve other symptoms

Other measures such as zinc ionization of the turbinates or the application of phenol have been used in an attempt to prevent the attack or as a method of cure during the attack Experience has now shown that these are not successful and may be dangerous Asthma which has never existed before has followed the use of these measures for the seasonal as well as the perennial type of disturbance

Specific Treatment —It has recently been shown that injections of pollen extracts in specifically sensitive hay fever patients induce definite serologic changes These are demonstrated by the newer methods of quantitative serum titration using nonsensitive test subjects for passive transfer The protection obtained by specific treatment does not appear to depend on desensitization for the amount of serum antibody remains the same or may even be increased The protective mechanism afforded by specific injections is not yet completely understood

Prophylactic Treatment —The specific treatment of hay fever by means of pollen extracts is well established Having first determined by means of the tests the proper pollen extracts to be used and the degree of sensitiveness of the patient to these pollens as outlined under Diagnosis treatment is begun with subcutaneous injections about ten weeks in advance of the expected attack Increasing doses are given at approximately weekly intervals according to the Table of Suggested Dosage

The maximum dose which is attained at or about the period of clinical onset is given weekly without further increase throughout the season With the earlier doses there is usually some reaction at the site of injection with swelling and itching lasting fo twelve to twenty four hours If the local reaction persists longer than forty eight hours the subsequent dose should not be increased for fear of a general reaction

Phylactic Treatment —Phylactic treatment is necessary when patients apply for treatment during or just before the onset of the attack Here the same method of diagnosis by means of the cutaneous test is necessary The ophthalmic test is useless after the attack has begun The injections are carried out according to the Table of Suggested Dosage and maximal doses are continued every three days to the end of the season

Perennial Treatment —With the idea that long continued injections lead to better results and may eventuate in a permanent *cure* patients prophylactically treated to a maximal dose are continued under treatment with a maximal injection every three to four weeks throughout the year Such monthly injections must be given for several years This type of therapy is not applicable to all cases

Constitutional Reactions —These begin very quickly after the injection sometimes within a few minutes practically always within an hour The sooner they begin the more severe and the more dangerous they are The symptoms of these reactions

are first itching of the palms of the hands then rapidly developing general erythema and urticaria with marked coryzal symptoms and asthma Occasionally there is edema of the eyelids and of the face Asthma is the symptom that makes any reaction dangerous and an asthmatic attack may result even if there is no clinical history of asthma with the hay fever itself These constitutional reactions should be immediately recognized and a tourniquet applied very tightly above the site of injection in order *to delay further absorption into the general* circulation The patient is then treated by a liberal subcutaneous injection of epinephrine (1 1000 solution in amounts of 0.5–1 cc) This should be repeated frequently in order to control the attack If the attack is very severe the injection should be given intravenously No limit should be put upon the dosage for under these conditions enormous quantities are tolerated *Morphine* is also indicated in the usual dose In very severe attacks when there is indication of dilatation of the heart caused by the intense dyspnea *strophanthin* administered intravenously is helpful

RESULTS OF TREATMENT —The reason for the beneficial results from injection of pollen extracts has not yet been discovered It is not desensitization, for after a complete course of treatments the cutaneous and ophthalmic reactions are still obtained with about the same degree of intensity as before the treatment The effects of seasonal injections are not permanent The course of treatment must be continued from year to year although in general it is observed that the sensitivity tends to decrease after several years of treatment That the treatment is effective is demonstrated by the clinical results that have been obtained consistently *over a long period of years In 80 to 90 per* cent of the patients treated the coryzal symptoms are almost entirely eliminated but it is very difficult to secure their complete absence throughout the entire season In those patients in which asthma occurs as a part of the reaction the results are even more satisfactory In over 50 per cent of the patients with clinical asthma this symptom is entirely controlled The results of phylactic treatment are sufficiently good to warrant its use but they are not as good as those of prophylactic injections The results of perennial treatment are better than the seasonal but it is too soon to evaluate the chances of permanent cure by this method

SUGGESTED DOSAGE ACCORDING TO DEGREE OF SENSITIVITY

PROPHYLACTIC[1]			PHYLACTIC			
A[2] UNITS	B[3] UNITS	C[4] UNITS		A[2] UNITS	B[3] UNITS	C[4] UNITS
5	10	50	1st day	1	10	50
10	20	150	2nd day	1	10	50
15	40	300	3rd day	1	10	50
25	70	500	After 2 days	2	20	100
3	100	750	2 days	3	30	200
50	200	1 000	3 days	4	40	300
75	400	1 500	3 days	6	60	500
125	700	2 500	3 days	8	80	700
175	1000	4 000	3 days	10[6]	100[6]	1000[6]
250	1500	6 000				
300	2000	8 000				
400	3000	10 000				
600	4000	12 000				
800[5]	5000[5]	14 000[5]				

[1] Prophylactic doses given weekly
[2] A Very sensitive cases
[3] B Moderately sensitive cases
[4] C Relatively insensitive cases
[5] This dose is continued weekly to end of season
[6] This dose is given every three days to end of season

NONSEASONAL HAY FEVER

(*Perennial Hay Fever Vasomotor Rhinitis*)

Definition —This clinical condition differs from the seasonal type in its specific cause and in the fact that the attacks are not regularly seasonal, but may be continuous or paroxysmal throughout the year The pathogenesis functional pathology, symptoms complications diagnosis and diagnostic technic are the same as in the seasonal hay fever

Etiology —The most important excitants are

1 *Absorbed by inhalation*
   (*a*) Animal danders horse cat dog rabbit goat, cow, guinea pig chicken goose duck
   (*b*) Vegetable powders orris rice corn wheat seed of cotton kapok, flax castor bean dust of hay and straw (not pollen) hops
   (*c*) House dust
   (*d*) Spores of various fungi
2 *Absorbed by ingestion*
   (*a*) Foods milk egg wheat fish shellfish nuts chocolate coffee buckwheat celery bean white potato banana
   (*b*) Drugs quinine aspirin ipecac senna iodine morphine phenol phthalein
3 *Absorbed from focus of infection* Para nasal sinuses

When symptoms are caused by the ingestion of the allergen the coryzal symptoms are usually but the minor part of a general reaction with urticaria erythema angio neurotic edema asthma and gastro intestinal disturbance

Air borne substances absorbed by inhalation are the actual causes in most instances They are encountered in the home at work or casually The air borne substances listed above are the most frequent causes A reaction to animal danders may be caused by contact with animals or in the case of feathers by contact with pillows and upholstered furniture Contact with cotton seed and kapok is established by their presence in bedding Orris root rice powder and cornstarch are frequent ingredients of cosmetic powders Cereal flour acts rarely after ingestion, usually by inhalation and is, therefore a more common cause of the disturbance among cooks and bakers House dust is probably the commonest specific agent and the irritant seems to be different from all the known substances and as yet has not been identified The dust of hay or straw is distinct and bears no relation to their respective pollens It is an etiologic factor among farmers and those who sleep on bedding made of grass and straw Spores of fungi are unquestionably important They are especially prevalent in the summer and so may give a seasonal appearance to the coryza but since they do exist and may be isolated from the dust of houses at all times of the year they are properly classed as agents of perennial hay fever

In properly allergic cases acute upper respiratory infection or the exacerbation of a chronic sinusitis may cause typical attacks of vasomotor rhinitis Hyperplastic rhinitis and sinusitis with or without polyposis represent a special type of reaction to infection in allergic individuals

Treatment —The diagnostic tests are carried out by the scratch or intradermal methods used for seasonal hay fever It is particularly important in this type however to determine not only that an individual reacts to the test and that the reaction can be verified at will but also that the individual has actually come in contact with the reacting substance and that it is truly the exciting cause In other words one must differentiate between *actual* and *potential* excitants

The therapeutic principle best applied to the management of these cases is *strict avoidance of all contact with the actual excitants* If the reaction is to feathers all chance of contact with feathers must be removed Particular attention must be paid to cleanliness and the home should be kept as free from dust as possible At times change of occupation is required Foods if causative agents must be eliminated from the diet When contact cannot be avoided treatment by injection may be employed It must be continued for a long time *hence* the advantage of the perennial form of treatment that is injection every three or four weeks once maximal doses have been reached

Treatment of the infective type requires the special attention of the rhinologist Vaccine injections may help

ASTHMA

Definition —Asthma is dyspnea of a characteristic wheezy type caused by obstruction to the flow of air in and out of the lungs Such wheezy breathing occurs in a variety of conditions and may be either continuous or paroxysmal hence the term *asthma* should be used to indicate not a disease but a symptom *Bronchial asthma* is a term which is loosely applied to a syndrome exhibited by patients who between attacks of asthma are subjectively and objectively well

History.—Asthma was familiar to various Greek and Roman authors though the attacks of severe wheezing were confused with dyspnea of other causes In Sir John Floyer's "Treatise of the Asthma" published in 1698 there is an interesting account of his own symptoms Although John Bostock in 1819 discussed the effluvium of new hay as the cause of *Catarrhus Aestivus* and Blackley in 1865 demonstrated that itching swelling and edema followed the application of pollen to the skin of patients with hay fever and asthma the relation of the pollens animal danders and other dusts to the symptoms were not considered until the work of Dunbar in 1905 In 1906 Wolff Eisner demonstrated the specificity of pollens and initiated the study of pollen chemistry Von Pirquet's description of serum disease appeared in 1905

In 1910 Meltzer recognized that the symptoms and pathology of anaphylactic shock in the guinea pig were quite similar to those of asthma During the next few years many different authors described the symptoms which follow contact with particular proteins in susceptible individuals H L Smith's case of buckwheat poisoning was described in 1909 Schloss study in 1912 of a child sensitive to egg white and to almonds is classical In 1914 Goodale demonstrated that the application of horse dander to the turbinates causes an acute attack in horse asthmatics After that, Talbot Walker Cooke Longcope and others brought out the value of skin tests and clinical allergy became of practical importance in internal medicine

Incidence —Asthma is a common disease It occurs in individuals of all *ages* and *races* The *sexes* are about equally affected

Etiology —The causes of asthma are manifold They group themselves like the parts of a tree The trunk represents a fundamental basis which may be called the asthmatic state which explains why some individuals have asthma and others do not This trunk depends perhaps on several roots one of which we recognize as inheritance for it is known that in at least 40 per cent of cases someone in the family has had hay fever asthma urticaria or some peculiar susceptibility to a food or odor The other roots are unknown Upward the tree trunk divides into two main branches the first includes those individuals whose asthma is due to some cause outside of the body to which they are hypersensitive (the extrinsic group) the other includes those not demonstrably hypersensitive where the cause is apparently inside the body (the intrinsic group) Reports of the relative percentage of cases in the two groups vary greatly presumably because the clinical material varies in age and in the type of asthma predominant in different clinics More than 75 per cent of all asthma is extrinsic

Extrinsic asthma implies that the cause of trouble is some foreign substance to which the individual is hypersensitive The basic cause is allergy The occurrence of *occupational asthma* is evidence that hypersensitiveness is acquired presumably only by susceptible persons The precise cause thus depends upon environment

Hypersensitiveness is demonstrated in at least two ways (1) Clinically by showing that symptoms occur after contact with the offending substance (2) By skin test scratch or intracutaneous as will be described presently Eye tests and nasal tests are sometimes used

In extrinsic asthma contact with the foreign substance may be brought about by inhalation by ingestion or by injection into the skin Of these various methods inhalation *of dusts* is by far the most important in

adults, while ingestion *of foods* plays the important role in children Injection is mentioned because *in the specific treatment of* hay fever, asthma may be produced by an overdose of pollen extract

DUST ASTHMA (BY INHALATION) has many *causes which can be divided* into groups The first is that of *pollens* Trees grasses and weeds may each and all be important but their relative value depends on locality In *southwestern United States* the pollen season is long with grass pollen in the air almost all the year In New England the season is shorter Trees produce pollen in *quantity but each one only for a few days* in the month of May Tree pollen asthma is rare although it may be severe Grasses begin to pollinate in late May and grass *pollen is demonstrable in the air until after* August 1st Many patients have hay fever and asthma from grasses Ragweed is abundant east of the Rocky Mountains and its *varieties cause much trouble in August and* September and until after frost

MOLDS notably the fungi of the imperfect genera produce spores in large quantities *especially in the late summer and fall and* it is quite likely that these play a part in certain complex cases

DANDERS AND EMANATIONS FROM ANIMALS *constitute another important group of* etiologic agents Fur is sometimes as bad as the living animal itself Feathers in pillows are important

OCCUPATIONAL DUSTS constitute an important group Bakers and housewives may have asthma from wheat flour Cotton, wool leather malt orris root ipecac flaxseed and glue have all been described as causes of asthma and the list grows with the development of complex chemicals used in modern industry Dyes solvents bleaches developers fixatives and other substances may cause allergic symptoms usually of the skin Occasionally they cause asthma

HOUSE DUST represents from the practical point of view the greatest source of trouble Many patients have been cured of asthma by the elimination of kapok called silk floss in pillows mattress and over stuffed furniture Cotton dust is less important Curled horse hair is safe in almost all instances, for patients with frank horse asthma can sleep on a horse hair mattress without difficulty The new mattresses made of sponge rubber are promising

FOOD ASTHMA (BY INGESTION) is not common except in children The important offending foods are the common foods—eggs wheat and milk After these three the other foods or drugs cause trouble in only occasional cases It is difficult to prove clinically that one food is more responsible than another for the asthma a fact which perhaps explains the confusing reports in the literature

Multiple sensitiveness is the usual rule and patients may be sensitive not only to a pollen and to an animal dander but also to some article of food and all at the same time

Intrinsic asthma is a term which implies *that the cause of trouble is inside the body* the patient carries it with him regardless of changes in season residence occupation or diet This is the difficult group which we describe as dependent upon some X *factor'* In this group 20 out of 283 patients (7 0 per cent) have died of asthma, whereas in the extrinsic group no death from asthma *has occurred There are several* types of cases

1 Intrinsic asthma may develop on a *background of extrinsic asthma*—the attacks *becoming more frequent* and more severe until the patient is no longer relieved by a change in environment or by admission to the hospital

2 HEAD COLDS LEAD TO ASTHMA —Children who wheeze with colds are often slightly sensitive to some dust substance and the cold makes the subclinical sensitiveness effective In older persons the term asthmatic bronchitis is descriptive the attack depends upon a true bacterial allergy Adults with varying degrees of emphysema or chronic bronchitis have severe asthma with every cold On the other *hand* severe infections with fever like pneumonia may cause asthma to disappear at least temporarily a fact which is of considerable theoretical importance

3 A SUDDEN ONSET OF INTRINSIC ASTHMA may occur after the age of forty five more often in men than in women It may follow an acute *respiratory infection* or it may come without obvious cause This group is hard to treat In the hospital these patients

improve but they do not show the dramatic change exhibited by those extrinsic cases which have escaped from a dust which was causing trouble at home

4 CHRONIC PERSISTENT VASOMOTOR RHINITIS sometimes leads to asthma and so creates a systemic disease of serious prognosis

In intrinsic asthma the cause may lie not in the respiratory tract but in some other part of the body Thus

REFLEX CAUSES arise from lesions in the nose and sinuses About one half of our cases of intrinsic asthma are found to have lesions of the paranasal sinuses varying from thickened membrane to a full blown pansinusitis of the polypoid type and most of them have already had operations on nose or sinuses obviously without relief The high proportions are good evidence that these lesions are part of the picture of asthma and not a cause of it Nevertheless there are a few cases in which operations on the sinuses or even the removal of nasal polypi have brought prompt relief Furthermore there is evidence that a true nervous reflex can exist with the afferent impulses arising in scar tissue in the region of the sphenopalatine ganglion

TOXIC CAUSES arise from focal infection We have seen patients quite relieved of chronic asthma by operations on the appendix or gallbladder or pelvic organs as well as more commonly by the extraction of abscessed teeth or by tonsillectomy Constipation *as a cause belongs in the same category* Also to be included are the rare cases with a positive Wassermann whose asthma clears with antisyphilitic treatment

NEUROTIC CAUSES probably exist Cobb and his associates have described several patients in whom the history and course were so bizarre as to preclude any explanation other than a neurosis On the other hand we see many patients who appear nervous and apprehensive with their asthma but who have become normal again when more careful study has resulted in the elimination of the feather pillow some toilet powder or a household pet In these cases the nervousness is presumably an effect of the asthma and not the cause of it In a few cases however nervousness with the poor hygiene which goes with it may account for the whole picture In children treatment by such simple measures as a mid-day rest a glass of milk between meals more outdoor air, less sympathy and better discipline from the mother have been enough to relieve the symptoms even without changes in diet or environment In certain adults the onset of asthma has coincided with a severe emotional strain and such cases have been difficult to treat especially if there was also a marked physical strain as might be produced for example by a long illness and death in the family

CARDIAC ASTHMA AND RENAL ASTHMA are terms descriptive of the underlying cause in a few cases but as pointed out by Harkavy diseases of the heart and arteries may coexist with asthma the cause of which is entirely separate and independent

Whatever the original cause of asthma *secondary infections of the bronchial mucous membrane* are prone to develop Pollen asthma which ordinarily is relieved by the first frost of autumn may because of a secondary infection continue into the winter

Morbid Anatomy and Physiology—The symptom asthma depends upon an obstruction to the flow of air in and out of the lungs This may be due either to a spasm of the bronchial muscles to edema of the bronchial mucous membrane or more important to masses of sticky mucus in the bronchial lumen

The bronchial muscles are arranged spirally to form a lattice like structure around *the tubes as Miller has described Asthma* may be due either to the contraction of this lattice structure and the consequent closing of the small bronchiolar openings between its fibers or it may be due to the contractions of the minute sphincters about the infundibula More recently T B Mallory has found that in patients dead of asthma the entire bronchial tree is filled with tough sticky exudate which can be pulled out in long rubbery strands The plug has a fairly definite structure there is little or no reaction in the surrounding lung no evidence of infection and there is an increase in the number and size of the mucous glands an expression of the overactivity of these glands which results in the outpouring of excessive secretion into the bronchial lumen

The physicochemical mechanism by which

asthma is produced is so far unknown Whereas the clinical picture is relatively uniform, it is brought about by a wide variety of exciting causes The asthma due to extrinsic factors—pollens animal danders, kapok, house dust and even foods—appears to be a single disease entity and therefore, one thinks of a common mechanism Histamine as the intermediary factor has been suggested for three principal reasons (1) the injection of histamine into normal animals or man can produce asthma (2) Lewis

Fig 45—Cut section of lung from case of bronchial asthma *Note the tough white plugs protruding* from many of the larger bronchi Note also the scattered white slightly elevated areas representing plugs in the smaller tubes The whole lung is emphysematous and of uniform texture

has produced circumstantial evidence that injuries can cause many cells to release the histamine like substance which they normally contain and (3) Weiss and others have shown that *patients with asthma react* more violently to the intravenous injection of histamine than do normal persons Hence the theory that the specific antigen antibody reaction called allergy taking place on the surface of cells results in the release of histamine which in turn causes the stimulation of bronchial muscles and glands to produce asthma Other substances beside histamine could fill the same function Acetylcholine is also a normal constituent of cells and there may be other substances with similar attributes The histamine theory is interesting because the same mechanism can be invoked by exciting agents other than allergens The writer believes therefore that allergy is an important cause of asthma but that it is not the only cause

In the production of reactions in passively sensitized skin sites it has been shown that the reaction is obtained regardless of whether the antigen is inhaled (Cohen) ingested (Walzer) or injected into a contralateral site (Gay) These experiments help to explain food asthma on the same basis as pollen or dust asthma the antigen does not reach the cells by direct inhalation it is absorbed through the nose or stomach and enters the blood stream

Meantime it seems that asthma occurs only in certain individuals predisposed to it by inheritance or otherwise The increased *susceptibility to histamine suggests* a possible mechanism by which this predisposition may be expressed The point is that the problem of asthma probably lies more in the domain of physiology and chemistry than in that of immunology

The clinical picture of asthma is not limited to the pulmonary symptoms *Lesions of the paranasal sinuses* are part of it Thickened membrane polypoid sinusitis *purulent* sinusitis are all too common in the clinic and so whatever mechanism is found to explain asthma must explain sinusitis as well The latter is the result of the process and only rarely the cause of it *Eosinophile cells* in the blood sputum and nasal secretions are likewise characteristic of asthma In the blood the count may be as high as 50 per cent of the total leukocytes Eosinophilia may occur in both extrinsic and intrinsic cases and both during and between attacks In one group of very unusual cases studied by the writer the blood eosinophils were well over 50 per cent there was evidence of lesions of the blood vessels in addition to lesions of the bronchial and nasal mucous membranes The diagnosis of periarteritis nodosa was made and confirmed by biopsy and autopsy *Vascular lesions* may be another part of what can now be called the

asthmatic syndrome *Emphysema* is always present In most cases it is temporary, the process is still reversible but sometimes the barrel shaped chest the presence of em physematous blebs on the pleural surface and the development of chronic cyanosis show that emphysema has become a serious complication *Heart disease* is not common but there may develop a cor pulmonale or pulmonary heart disease sometimes called the emphysema heart due to increased resistance in the pulmonary circulation Hypertrophy of the right ventricle develops slowly and insidiously and when failure comes there is engorgement of the entire venous system with deep cyanosis polycythemia and other signs of decompensation

Symptoms —Bronchial asthma is characterized by wheezy breathing For example the patient with horse asthma goes into a stable Within a few minutes his eyes itch his nose runs and soon he coughs feels a tightness in his chest and breathes with difficulty The asthma thus induced may pass off in a few minutes or it may develop into a distressing picture forcing the patient to sit with his elbows on his knees and his head down so that every accessory muscle of respiration can be brought into action The expiration becomes long and noisy the inspiration difficult and with obvious effort The attack may last for many hours but when it is over he will be free so long as contact with horses is avoided

Patients with intrinsic asthma present a similar picture except that the onset and remissions are less abrupt and the attack once started may continue for days sometimes for weeks Exertion cold air dust or fumes aggravate the symptoms The patient may awaken from one to four times at night to cough and wheeze until relief comes through medication Occasionally he must spend the whole night in a chair in front of a small table over which he can lean and sleep between the paroxysms

Cough varies according to the amount of bronchial infection but at the end of the attack cough with the production of sticky sputum is characteristic *Sputum* varies in character according to the extent of secondary infection Cultures show organisms of all sorts with staphylococci predominating in the purulent varieties Influenza bacilli are also found in the thick sputum of patients with long standing bronchial infections Eosinophilic cells are characteristic features of asthmatic sputum *Hemoptysis* does not occur in simple asthma but is not rare in emphysema *Pain* is not common except as excessive cough and severe asthma produce a sore chest *Gastro intestinal* symptoms are rarely noticeable except in a few patients who are sensitive to foods Patients cannot eat during severe asthma and hence they usually lose weight

Physical examination in the typical extrinsic case without secondary infection shows rales which are dry musical and evenly distributed In other cases an uneven and variable distribution of moist rales indicates bronchial infection Loud bubbling rales heard in certain areas suggest plug formation Diminution of the breath sounds is the rule In emphysema the chest outline may be barrel shaped the percussion note is loud the lung bases appear to be low and the heart outline small because of the distention of the overlying lung *Cyanosis* is not present in simple asthma but occurs in patients with emphysema and bronchitis who suffer from a markedly increased dead space in the air passages Marked cyanosis is an important symptom of *cor pulmonale* when the right heart breaks under the excessive strain The *blood pressure* is normal but the systolic pressure often falls sharply during inspiration because of the increased negative pressure in the pleura during inspiration In the *blood* eosinophilia is characteristic The fasting blood sugar content and the sugar tolerance curve are both normal in asthma

Diagnosis —The diagnosis of asthma is usually made by the patient Between attacks there may be no evidence of disease but during attacks the wheezy dyspnea is so characteristic that diagnosis can be made on sight The long arduous respiratory phases cannot be confused with the dyspnea of pneumonia or cardiac failure

Asthma however is merely a symptom To find the cause of it there are three steps The first and most important is the *history* and in taking the history there are three essentials The first is to use dates in an orderly chronological record which should begin with the first wheeze The second is

asthma is produced is so far unknown Whereas the clinical picture is relatively uniform, it is brought about by a wide variety of exciting causes The asthma due to extrinsic factors—pollens animal danders kapok house dust and even foods—appears to be a single disease entity and therefore one thinks of a common mechanism Histamine as the intermediary factor has been suggested for three principal reasons (1) the injection of histamine into normal animals or man can produce asthma (2) Lewis

Fig 45 —Cut section of lung from case of bronchial asthma Note the tough white plugs protruding from many of the larger bronchi Note also the scattered white slightly elevated areas representing plugs in the smaller tubes The whole lung is emphysematous and of uniform texture

has produced circumstantial evidence that injuries can cause many cells to release the histamine like substance which they normally contain and (3) Weiss and others have shown that patients with asthma react more violently to the intravenous injection of histamine than do normal persons Hence the theory that the specific antigen antibody reaction called allergy taking place on the surface of cells results in the release of histamine which in turn causes the stimulation of bronchial muscles and glands to produce asthma Other substances beside histamine could fill the same function Acetylcholine is also a normal constituent of cells and there may be other substances with similar attributes The histamine theory is interesting because the same mechanism can be invoked by exciting agents other than allergens The writer believes, therefore that allergy is an important cause of asthma but that it is not the only cause

In the production of reactions in passively sensitized skin sites it has been shown that the reaction is obtained regardless of whether the antigen is inhaled (Cohen) ingested (Walzer) or injected into a contralateral site (Gay) These experiments help to explain food asthma on the same basis as pollen or dust asthma the antigen does not reach the cells by direct inhalation, it is absorbed through the nose or stomach and enters the blood stream

Meantime it seems that asthma occurs only in certain individuals predisposed to it by inheritance or otherwise The increased susceptibility to histamine suggests a possible mechanism by which this predisposition may be expressed The point is that the problem of asthma probably lies more in the domain of physiology and chemistry than in that of immunology

The clinical picture of asthma is not limited to the pulmonary symptoms *Lesions of the paranasal sinuses* are part of it Thickened membrane polypoid sinusitis purulent sinusitis are all too common in the clinic and so whatever mechanism is found to explain asthma must explain sinusitis as well The latter is the result of the process and only rarely the cause of it *Eosinophile cells* in the blood sputum and nasal secretions are likewise characteristic of asthma In the blood the count may be as high as 50 per cent of the total leukocytes Eosinophilia may occur in both extrinsic and intrinsic cases and both during and between attacks In one group of very unusual cases studied by the writer the blood *eosinophils* were well over 50 per cent, there was evidence of lesions of the blood vessels in addition to lesions of the bronchial and nasal mucous membranes The diagnosis of periarteritis nodosa was made and confirmed by biopsy and autopsy *Vascular lesions* may be another part of what can now be called the

the sulfate or the hydrochloride is helpful in the mild cases but may cause insomnia The inhalation of smoke of stramonium leaves the chief constituent of most commercial asthma powders and of asthma cigarettes often relieves the bronchial spasm and the edema Certain sprays for the nose and throat are also helpful Steam plain or medicated with tincture of benzoin may be inhaled Morphine should never be used Morphine itself gives a skin test in normal people it is a cholinergic drug and as such tends to increase the bronchospasm It may inhibit the respiratory center to a dangerous degree

To avoid drug allergy it is best to use drugs with simple chemical formulas The bromides chloral hydrate and paraldehyde are all useful Cathartics must be restricted to the various salts

Severe intractable asthma requires more strenuous measures If possible the patient should be moved to the clean environment of a hospital and preferably to a dust free room If epinephrine is not effective subcutaneously it can be given intravenously adding 1 cc of the 1 1000 solution to a liter of salt solution preferably with 5 to 10 per cent of glucose and taking at least an hour for the injection It should be remembered that too much adrenalin can cause auricular and perhaps ventricular fibrillation Aminophylline in doses of 0 25 Gm dissolved in 10 cc of water is often very effective when injected intravenously Aminophylline is also effective when given by rectum A dose of 0.50 Gm dissolved in 20 cc of tap water can be given each night if necessary Ether in olive oil an ounce of each mixed together and given by rectum is recommended and ether by inhalation to full anesthesia may abolish the paroxysm

The inhalation of helium with oxygen has been found effective in terminating intractable asthma Due to the low atomic weight of helium and the decreased pressure required for its transport through small orifices the effort of breathing becomes greatly diminished Barach recommends that a mixture of 20 to 35 per cent oxygen in helium be given by means of a mask or better a helmet hood in which a positive pressure of 3 to 5 cm of water is maintained by the pressure tank If anoxemia is marked the percentage of oxygen can be increased to 35 per cent Barach describes the advantages of producing bronchial relaxation' several times a day and he accomplishes this by three procedures Aminophylline is given by rectum The patient inhales as deeply as possible a fine spray of epinephrine in strong 1 to 100 dilution and then is given the oxygen helium mixture to breathe for periods of from one to four hours or until relief is obtained Straight 100 per cent oxygen is also very useful in desperate cases and can be employed for as long as twelve hours without harm The B L-B mask devised by Boothby and others is useful and efficient

Bronchoscopy to remove the sticky bronchial plugs by direct suction may be life saving in properly selected cases

A high fluid intake is always important and fluids should be given by vein or rectum if they cannot be taken by mouth

The Cause.—The discovery and elimination of the specific cause are in the present state of knowledge the chief objects of treatment The importance of kapok in cheap mattresses pillows and furniture has been described above Changes in bedding may lead to striking results The removal of animals face powder or rugs has brought relief in various cases Allergic cleanliness becomes necessary It applies to those items which are dust producers as well as to those which are dust catchers The laboratory worker sensitive to rabbits and guinea pigs remains free from attacks as long as he stays away from the animal room A patient with food asthma may be cured by elimination of the offending substances from the diet Rowe lays great stress on food even in patients whose skin tests to food allergens are negative and his elimination diets have been very effective in his hands They exclude the three foods which give the highest percentages of positive reactions—eggs wheat and milk It is proper to observe however that when wheat is taken from the diet a reduction of total carbohydrate usually results automatically and the writer believes that this change in the diet may well be important in modifying the fundamental background of the allergy

When the patient cannot escape the offending substance—the pollens in the hay fever season or the dusts in his industry—

to account for all the time It is often quite as *important* to know when and why the attack ended as to know when and why it began If there was a free interval without asthma the fact and the dates should be written down The third is to include the *dates of changes in residence* or *occupation* and the dates of operations or intercurrent diseases among the other dates of changes in symptoms When this is done the whole story can be seen in its broad aspects Two *small children both had asthma in summer*, in one the attacks began before the move to the seashore it was due to pollens In the other, asthma began on the first night of the move it was due to the kapok mat tress *in the summer cottage*

The second step is the *physical examina tion* The patient must be studied as a whole His size color nutrition and posture should all be noted What other disease is present besides asthma? Has he fever or cyanosis? The nose is important In hay fever the mucosa is swollen and pale A deviated sep tum may prevent the drainage of sinuses Nasal polypi indicate trouble and trans-illumination and x ray may show clouding in the sinuses All foci of infection not only in the head but in the abdomen and pelvis should be recognized promptly Pregnancy visceroptosis malnutrition syphilis and tu berculosis need only to be mentioned to em phasize the importance of treating the pa tient first his asthma second

The third step in diagnosis is the skin test The cutaneous or scratch test is easy to apply Powders or solutions are dropped on the skin and small scratches are made through them The intracutaneous method *is* much more delicate but requires a careful technic Sterile solutions in known concen tration are injected into the skin itself The solutions must be active so as to *give posi* tive tests in persons known to be sensitive and they must be nonirritating and give no reaction in normal persons With both meth ods a positive reaction consists of a wheal and *erythema* which appears within twenty minutes Controls are necessary and several tests with various substances should be ap-plied at the same time one to *control the* other When all the tests react the patient *is* said to have an irritable skin unless per haps the syringes or extracts are dirty chem ically while being clean bacteriologically In our clinic, a separate syringe is reserved for each extract used

Discrepancies between tests and symp-toms are all too common Positive tests may be found but with no symptoms to go with them They often represent the past history rather than the present illness The patient may have had hay fever previously but now only the positive skin test remains Nega tive tests in the face of a true clinical sensi *tiveness* sometimes occur *In* occasional cases, we have found that a retest later is positive so it would appear that sensitiveness devel ops in different tissues at different times Possibly this explains the finding of positive *eye (conjunctival) tests in a few patients* whose skin tests are still negative When discrepancies occur it is well to be guided by the history rather than by the skin test On the whole however, symptoms and skin tests are *consistent* in most cases

Tests to be of diagnostic importance must be correlated with the history in such a way as to make a logical and reasonable explana tion of the attacks Clinical experiments made either by changing the environment or by modifying the diet are frequently nec-essary before positive tests can be inter-preted

Prognosis —Patients with extrinsic asth ma do not die of asthma except in those rare cases in which an overdose of the spe-cific substance injected for test or for treat *ment has led by accident* to a very severe allergic reaction In the intrinsic cases how ever death from asthma has occurred in 7 6 per cent of cases

The hope of permanent relief depends entirely upon the discovery and the removal of the cause Whether the fundamental con stitutional basis for the allergy or for the *asthma can be modified or not is* so far quite doubtful Children particularly boys who develop their symptoms early have the best chance of outgrowing their trouble

Treatment —*The Attack* —The treat ment of an attack is usually simple Adren alin chloride injected subcutaneously can control almost any attack for a time varying *from minutes to hours* A dose of 0.25 cc of 1 1000 solution often works as well as 1 cc and the dose can be repeated at half hour intervals if necessary *Ephedrine either* a-

study of the clinical and immunologic phenomena of serum sickness was undertaken by von Pirquet and Schick their results were published in a monograph in 1905 Their work defined and illuminated the problem and has stimulated many others during the past thirty five years to investigate the incidence symptomatology and mechanism of serum reactions

Incidence.—Not every patient treated with serum develops serum sickness If amounts below 10 cc are used only about 10 per cent have symptoms but if 100 cc or more are administered only 10 per cent escape at least some manifestation of serum sickness The incidence therefore depends largely upon the amount of serum given but also in lesser degree upon other factors the preparation of the serum the horse producing the serum and the patient himself Race is also a factor Negroes and American Indians appear to be less susceptible than the white race Age sex the disease for which serum is given and the route of administration seem to have little or no effect on incidence The recent introduction of refined and concentrated therapeutic sera from which the serum albumin has been eliminated has because of the smaller amount of foreign protein injected caused a reduction in the incidence of serum sickness

Pathogenesis.—Precipitins for the foreign serum are usually in the circulation after the ninth or tenth day In severe cases they are apt to reach a high titer and in patients who despite large amounts of serum have little or no serum sickness they are usually absent *transitory or of low titer* When the precipitin in the circulation reaches a high titer the foreign serum still in the circulation disappears rapidly when no precipitin is demonstrable the disappearance of the foreign serum from the circulation is greatly retarded The symptoms of serum sickness are thought to be due to a union of the foreign serum with the specific precipitin which has been elaborated during the incubation period In addition to horse serum precipitins agglutinins and lysins for sheep cells appear in the blood of patients treated with horse serum The constituent of serum chiefly responsible for serum sickness seems to be the pseudoglobulin the euglobulin may also participate in the production of the symptoms the albumin fraction is apparently inactive

Symptoms—When serum is administered to an individual for the first time there is usually an incubation period of six to twelve days before the onset of serum sickness The incubation period may in rare cases last two or even three weeks In a small percentage of patients the incubation period may be less than six days, but in such patients it is not always possible to exclude the possibility of a previous and forgotten injection of serum such as an immunizing dose of antitoxin or toxin antitoxin injections in childhood Some of these individuals with shortened incubation period may have a spontaneous hypersensitiveness to horse serum of such low degree that neither a skin test nor the history reveals the hypersensitiveness

When large amounts of serum are administered the *severity of the symptoms* is determined chiefly by the constitutional susceptibility of the individual A liter of serum given during the course of two or three days may produce nothing more than a few urticarial wheals and slight enlargement of the superficial lymph nodes for a day or two Other patients after receiving a few cubic centimeters of serum may have severe urticaria edema fever arthritis and swollen tender lymph nodes for one or two weeks Exceptionally the symptoms persist for three weeks or longer In a large proportion of patients they subside in less than a week When such amounts of serum as are commonly employed in diphtheria and tetanus immunization have been administered the severity as well as the incidence of symptoms tends to be less than after the large amounts given for pneumonia and meningococcus meningitis But even after small quantities of serum given subcutaneously an occasional patient may have severe and prolonged serum sickness

Serum sickness without *skin manifestations* is very rare The eruption is usually urticarial or a mixture of urticaria and erythema Itching of the skin often comes first, then patches of erythema and discrete wheals appear the wheals with a circumferential zone of erythema may remain discrete or as the eruption becomes more intense large wheals the size of the palm of the hand appear and by confluence form bizarre patterns over the chest back or ex

specific desensitization can be attempted by giving a series of inoculations with the corresponding extract The technic is difficult the dosage is hard to gauge and general constitutional reactions sometimes of considerable severity are prone to occur Furthermore it is our experience that the desensitization produced is usually relative and temporary The extract used should contain the specific substance which has caused the symptoms

The cause of intrinsic asthma is unknown but much can be done to relieve the patient The removal of focal infections in teeth tonsils sinuses gallbladder pelvis and even prostate has helped various individual cases The *relation of paranasal sinusitis to* asthma has already been discussed Sinus operations have helped a few cases usually for a temporary period, but the later results are often disappointing Nevertheless it is important to secure nasal drainage by removal of polyps and other simple procedures but it is also important not to disturb the normal structure and function of the nasal mucosa

Injections of nonspecific substances like peptone milk crotalin, the patient s own blood, and various vaccines are often helpful Good results seem to go hand in hand with the production of a local reaction at the site of inoculation Such treatment is capable of aggravating the asthma just as mild respiratory infections may Severe infections, however, such as pneumonia are *always followed by a temporary disappearance* of the asthma hence one form of treatment is to raise the temperature artificially by radiant heat or short wave or by giving typhoid vaccine intravenously Fever therapy is a rather drastic form of treatment for the asthmatic and not without danger

Potassium iodide is always useful in asthma It stimulates expectoration and so modifies the formation of tough sticky plugs Sometimes however it stimulates to the point of irritation and so may do harm Vitamins and hormones have each and all been considered and tested but so far with little success Acids and alkalis have both been given with doubtful results Deep x ray therapy has brought improvement to an occasional case The operations of sympathectomy and of vagectomy are disappointing

Finally, it should be said that whereas treatment of the asthma is important treatment of the patient as a whole is more important For asthma, the physician must be a doctor in every sense

SERUM SICKNESS

Definition —Serum sickness is an allergic reaction resulting from the parenteral administration of a foreign serum and characterized by an incubation period skin eruptions enlargement of lymph nodes fever edema and polyarthritis It should be distinguished from the immediate shocklike *and sometimes fatal reactions which occur* when foreign serum is administered parenterally to an individual who is hypersensitive to the serum employed These *latter* reactions are better called serum accidents Individuals slightly sensitive to horse serum may exhibit transition forms which present themselves as delayed serum accidents or as serum sickness with shortened incubation period

History —Although animal blood had occasionally been used in transfusions since the seventeenth century and various untoward effects noted not until 1875 (Landois and Ponfick) was there any appreciation of the important difference between human and animal blood for transfusions Generalized urticaria ten days after transfusion of alien blood was reported in 1874 (Dallera) but its significance was not understood *When diphtheria antitoxin* came into general use in 1890 the symptoms of serum sickness and serum accidents soon attracted widespread attention At first they were ascribed to the antitoxin content and then to some other unknown constituent of the horse serum but Johannessen (1895) showed *that normal* horse serum was equally effective The first systematic

ent serum proteins occurs at different times, and Coca found no relapses in 120 patients with serum sickness due to a diphtheria antitoxin consisting of the isolated pseudoglobulin

Diagnosis—Very rarely is there any difficulty in recognizing serum sickness Occasionally a relapse with an atypical or inconspicuous eruption may cause uncertainty It is sometimes difficult to decide whether fever occurring during or immediately after a serum eruption is due to a complication of the disease for which the serum was given or to the serum sickness A leukocyte count below 12 000 or an eosinophilia is in such cases evidence in favor of serum sickness

Prognosis—Fatalities from serum sickness itself are unknown Complete recovery, even from the severe forms is almost invariable provided the infectious disease for which the serum was administered leaves no permanent ill effects A high percentage of individuals retain for years some degree of sensitization to the serum employed yet with proper precautions the same kind of serum can be administered subsequently to nearly all of these patients

Rare neurologic complications such as neuritis polyneuritis transitory mono or hemiplegias have been described mainly by French observers

Treatment—It has not been demonstrated that serum sickness can be prevented Calcium and histaminase seem to be useless A certain amount of symptomatic relief is the most that can be expected For the pruritus calamine lotion containing 1 per cent phenol is often helpful Bicarbonate of soda baths may give temporary relief in severe cases Hypodermic injections of epinephrine (0 3–0 6 cc of the usual 1 1000 dilution) will usually give transitory relief from the pruritus Ephedrine (0 025–0 05 Gm) given by mouth three times a day before the onset of symptoms appears also to mitigate the symptoms Derick Hitchcock and Swift have shown that antirheumatic drugs given in adequate doses (6–10 Gm a day) from the time of the serum injections will keep the antihorse precipitin in the patient s serum at a lower titer than would otherwise be the case and will also prevent or lessen the severity of the arthritis

SERUM ACCIDENTS

Definition—Serum accidents are the immediate shock like sometimes fatal reactions which occur after the parenteral administration of a foreign serum

Etiology—The essential cause of these reactions resides in the specific reactivity of the individual Persons susceptible to asthma or to rhinitis and coryza when close to horses are most likely to have serious serum accidents Those sensitized by a previous injection of serum may also have alarming or, rarely even fatal reactions but in general are less sensitive than the horse asthmatic group Certain individuals also who have never experienced symptoms from contact with horses and who have not received a previous injection of serum show positive skin reactions to horse serum and hence must be considered hypersensitive Very rarely even the intracutaneous test for sensitivity may if the individual is highly sensitive and the test solution is not sufficiently dilute cause an immediate fatal reaction

Pathogenesis—Despite certain dissenting opinions most competent authorities look upon serum accidents as examples of anaphylaxis The fact that the majority have occurred in spontaneously hypersensitive individuals upon the first injection of serum has been urged as a reason for separating this group of serum reactions from anaphylaxis In those cases in which the first serum injection is tolerated without immediate symptoms and a subsequent serum injection after weeks or months has unloosed immediate and violent symptoms the analogy with experimental anaphylaxis is nearly complete The chief discrepancy is found in the phenomenon of desensitization

Pathology—Postmortem examinations have shown inflated voluminous lungs with acute emphysema and rupture of the inter alveolar septa the viscera are congested small hemorrhages into the myocardium and the adrenals and into the interstitial tissues of the lungs and kidneys have been described The right ventricle is apt to be greatly distended with blood and the left ventricle contracted and empty Efforts to incriminate the thymus in these fatal serum accidents have been based on tenuous evidence

tremities The face is usually affected Itching is often intense Occasionally the eruption is morbilliform or scarlatiniform but these atypical varieties are more often seen during a relapse than during the *initial sickness* Purpuric rashes are occasionally observed in serum sickness of more than average severity The eruption usually disappears after three to five days When the serum has been administered subcutaneously or intramuscularly the earliest eruption is apt to be at the site of the injection It may *remain confined* to this area—the so called 'local serum sickness —or subsequently become generalized

Slight or moderate enlargement of the *superficial lymph nodes* is usually present Often this *is the first symptom antedating* the eruption by one or two days The nodes may or may not be tender Frequently the epitrochlears are the first nodes in which the enlargement can be felt After the other symptoms of serum sickness have subsided the nodes often remain enlarged for several days When the serum has been administered *under the skin or into the muscles* the regional nodes are apt to be the first to increase in size Slight enlargement of the spleen is not infrequent

After large amounts of serum 50 to 60 per cent of patients with serum sickness show some evidence of *arthritis* In most cases objective changes are slight or absent The patient *complains of pain and stiffness* but there is little to be seen or felt In a small proportion of cases the joints are swollen hot red and distended with an exudate which has an interesting similarity to the joint fluid of rheumatic fever (Swift and Boots) It is turbid and contains leukocytes up to or above 20 000 per cubic millimeter *Polymorphonuclear* cells usually predominate A precipitin test often reveals the presence of horse serum in the joint exudate The commonly involved joints are the knees ankles elbows wrists and small joints of hands and feet Less commonly the other joints are affected The temporomaxillary joints are involved more often in serum sickness than in rheumatic fever It is unusual for joint symptoms to appear at the onset of serum sickness

Fever occurs in about one third of the cases From an elevation of only 1° F for a day or two all graduations are observed In severe cases the temperature *may reach* 103° or 104° F every day for a week or ten days There is no constant or typical temperature curve Frequently it is very irregular and remittent

Edema occurs also in about one third of the cases, it is more frequent in children than in adults The face sacral and pretibial regions ankles *hands and arms are the* areas where it is most often noted Chloride and water retention a lowered phthalein excretion moderate oliguria albuminuria and cylindruria are not unusual concomitants of the edema Rarely if ever is there a measurable *nitrogen retention* After the serum sickness has subsided all evidence *of impaired renal function vanishes* Attempts to demonstrate horse serum in the urine have been unsuccessful *Optic neuritis* with a slight increase of the cells and globulin in the spinal fluid may be observed occasionally Neuritis and other disorders of the nervous system occur in rare instances

In adults there is frequently no change in *the blood picture Von Pirquet and* Schick found that children show a leukocytosis during the incubation period and leukopenia after symptoms develop Such changes rarely occur in adults Even severe cases may show nothing abnormal in the blood count or there may be a slight leukocytosis while symptoms are present and toward the end or *after the period of symptoms* an increase of the eosinophile cells The sedimentation rate is usually unaltered

Other symptoms occasionally observed without any other explanation than that they are a part of the serum sickness are abdominal pains vomiting diarrhea stupor headache conjunctivitis and sore throat

Relapses occur in our experience after a free interval of from four to fourteen days With a recurrence of symptoms the eruption *is more apt to be erythematous* morbilliform or multiform than urticarial Any of the other symptoms may be present There are two observations supporting *the belief* that relapses represent reactions to antigenic constituents of the foreign serum different from those responsible for the initial *out*break of symptoms Dale and Hartley showed that when an animal is sensitized to a foreign serum sensitization to the differ

ANGIONEUROTIC EDEMA

Definition—Angioneurotic edema is characterized by transient circumscribed edematous swelling of the skin or mucous membrane *occasionally of the viscera Individual* lesions persist from a few hours to a few days and may occur either without sensory phenomena or with itching burning or prickly sensations One form is hereditary and frequently terminated by a fatal edema of the glottis another form is relatively benign and in some cases is dependent upon a *demonstrable food allergy Urticaria and* angioneurotic edema are frequently associated

History.—Under the title akutes umschriebenes Hautodem Quincke in 1882 described the nonhereditary form. Priority has usually been assigned to him although Milton in 1876 described the same condition under the title of Giant Urticaria" The first descriptions in American literature were from Osler who reported a *remarkable family history in which the disease* was transmitted for five generations

Incidence—The condition is not rare Bulloch in 1909 collected 170 cases from the literature

Etiology—*From Quincke s time* belief in an angioneurosis as the important pathogenetic factor has persisted and certainly in many of these patients psychologic difficulties *appear to participate in the etiology* Recent evidence makes it probable that in some of the *nonhereditary* cases the condition is due to *food allergy* The offending food can however be discovered only ex*ceptionally from skin reactions* these usually yield no helpful information This form is frequently associated with urticaria Focal infection and endocrine disturbances have been thought to be etiologic factors in some cases but critical scrutiny of the evidence in any series of these cases leaves a large percentage in which the etiology must be said to be undetermined *The sexes* are about equally affected No age is immune but *onset* at puberty has been noted in numerous cases The *hereditary form* of the disease may be transmitted through several gen*erations by both affected and unaffected* individuals without sex linkage The families studied do not show transmission according to the theoretical expectations of a Mendelian dominant It has been suggested that urticaria and angioneurotic edema are dependent on the same mechanism that in the former the superficial vessels of the skin are affected and in the latter the deeper vessels The mechanism which produces both of these cutaneous reactions seems to consist of vasodilation and transudation, the vasodilator substance is probably histamine —*free or in loose combination*—*or a hista*mine-like substance The mechanisms involved in wheal formation have been thoroughly studied by Lewis Recently Rose has reported a marked diminution of the histamine content of the blood when acute symptoms of angioneurotic edema were present

Symptoms—The *swellings appear as it* were spontaneously An itching prickly or burning sensation may precede the appearance of a smooth rounded elevation varying in size from a few millimeters up to large areas covering nearly the entire back The swellings may be tense and elastic or soft and pitting The skin may not change in color over the swelling *or may become pink* or dusky red Areas commonly involved are the lips the skin about the eyes chin hands feet, and tongue but any portion of the body surface may be affected A swelling may persist several days but more frequently dis

Symptoms —The onset of symptoms may be lightning like Almost before the needle is withdrawn local itching and edema develop A feeling of apprehension generalized urticaria often sneezing and a prickly sensation of the throat edema of face, hands neck or perhaps of the whole body cyanosis, choking sensation, cough and violent asthma are common symptoms The pupils dilate the pulse becomes thready or imperceptible, the temperature rises, convulsions may occur and the patient may be *dead* in less than ten minutes, in other fatal cases several hours may elapse between injection and death If the serum accident does not terminate fatally, the symptoms may become those of serum sickness at once or after a free interval of several days Other types of immediate untoward reactions to serum are (1) a thermal reaction characterized by an abrupt rise in temperature with or without a chill or chilly sensations (2) a shock like syndrome characterized by rapid weak pulse cold moist skin and low blood pressure without the more characteristic symptoms of the type of serum reaction commonly believed to be anaphylactic An abrupt fall of blood pressure is a frequent early sign of an impending serum accident

Treatment —The prophylaxis of serum accidents consists of (1) recognition before administering serum of those who are hypersensitive (2) desensitization of hypersensitive individuals

A history of asthma or hay fever should make one extremely cautious in giving serum particularly if the patient has experienced such symptoms when near horses or in stables A history of previous serum administration also calls for precautionary measures An intracutaneous test with a 1 10 solution of horse serum should always be made If this is positive the patient should be considered an unsafe subject for serum therapy by routine methods

Desensitization offers a method of administering serum safely to many patients who would otherwise react violently or even fatally if the whole amount of serum were injected in the usual way The genuine 'horse asthmatic *is often so highly sensitive* that he cannot be desensitized with such individuals even minute amounts of horse serum may endanger life but most of those whose hypersensitiveness dates from a previous serum treatment can in the course of twelve to twenty four hours be rendered sufficiently tolerant to take therapeutic quantities without danger If there is a history of asthma or a strongly positive skin test, the first desensitizing dose should be given *subcutaneously* Beginning with 0 005 to 0 025 cc according to the intensity of the skin reaction the dose may be doubled every half hour until 1 cc is given *Then 0 1 cc is injected intravenously* Dilution with normal salt solution is advisable because thereby injection may be made more slowly

The *intravenous* dose should be doubled every twenty to thirty minutes until the required amount has been given In case anything more than a mild reaction occurs one should wait the usual interval or longer and then repeat the last dose which produced only a mild reaction or none at all With some patients the desensitization program may be carried to a certain point but no further reduction of the dosage and subsequent gradual increase result in a reaction when the dose which previously caused a reaction is reached and repetition of this dose four or five times may be followed each time by a general reaction

If the serum is to be administered *intraspinally* the same procedure should be carried out until 5 or 6 of the intravenous doses have been given Then with diluted serum the intraspinal route may be tried slowly and cautiously With patients only slightly sensitive, as often proves to be the case when hypersensitiveness has been artificially produced by a previous serum treatment the desensitization program outlined may be shortened by starting with a slightly larger dose and increasing the size of the doses a little faster

One should always have on hand when attempting desensitization a syringe containing *epinephrine* ready for use Epinephrine is a specific for serum accidents Subcutaneous injection of 0 3 to 0 8 cc (5–12 minims) will usually prove effective in the milder accidents Injection should be repeated after a few minutes if necessary If the symptoms are alarming larger doses are indicated

George M Mackenzie

such as that from poison ivy which are easily dissolved in the fatty substances of the skin surface dyes which become fixed in the horny layer and come in close contact with the epidermis and local anesthetics such as procaine which have an affinity for epidermal structures Thousands of contactants have been identified as responsible for dermatitis They are associated for the most part with industry and trades The disease occurs frequently in bakers beauty parlor operators chemists exterminators furriers gardeners jewelers metal polishers munition workers nurses painters photographers printers tanners etc

Skin Responsiveness—Although quantitatively there is a wide variation in the capacity of the skin of different individuals to react no one is considered immune provided the epidermis is exposed sufficiently to repeated application of a known contactant The mechanism by which the skin becomes sensitized is wholly unknown No immune bodies have been discovered

Morbid Anatomy—The essential lesion is epidermal edema This occurs apparently as the result of an escape of fluid from dilated blood and lymph capillaries at the site of irritation As fluid continues to accumulate vesicles are formed within the epidermis and appear on the surface of the skin as small blisters In the more chronic stages prolonged rubbing may lead to hyperkeratosis and lichenification

Symptoms—The only symptom is pruritus felt as itching and burning at the site of the lesion In the acute cases there appears first an erythema with superimposed papules and then vesicles The time of appearance of the eruption following the initial contact is extremely variable Once hypersensitiveness is established however the lesion usually appears within twenty four hours after the last exposure In acute cases such as poison ivy itching may be felt within a few minutes in these cases scratching may convey the irritant to other parts of the skin In some instances where the process is very acute a generalized eruption may appear presumably from systemic absorption When there is continual contact as in certain industries the vesicular eruption is replaced by thickened fissured dry dermatitis Secondary infection is common

Differential Diagnosis—This concerns (*a*) the distinction from other types of eczema and (*b*) the detection of the specific contactant

Contact dermatitis may resemble the lesions of other types of eczema particularly atopic dermatitis which however is frequently associated with other atopic disorders as asthma and hay fever and this type of allergy is hereditary It occurs most frequently in infants and children and sites of predilection are the face neck and folds of the elbows and knees Contact dermatitis occurs most frequently in adults The distribution of the lesion frequently indicates the diagnosis and may even suggest the contactant at fault Thus an eczematous eruption limited to the skin about the eyes strongly suggests a cosmetic as mascara that which occurs only on the neck is frequently caused by fur dyes and that beneath the arms from dress shield material Other eczemas rarely have such a distribution

Detection of the offending contactant is made from the case history and from patch tests The site of the localized lesion suggests what the exposure might be and meticulous questioning will frequently elicit a clue The possible contactants are then applied to uninvolved skin Unlike intradermal tests the patch test material is gently rubbed onto the skin moistened if necessary covered with cellophane and held in place with adhesive material for twenty four to forty eight hours or less if intense itching occurs at the site of the test A positive reaction is an eczematous dermatitis at the patch site The contactant at fault will be revealed in about 40 per cent of the cases tested Precautions to be carefully observed are the removal of the patch if itching becomes marked and limitation of the number of tests at one time to twenty or less Necrosis of the skin and marked exacerbation of symptoms may occur if the application is too intense

Prognosis—All cases eventually recover sometimes quickly after the offending substance is removed

Treatment—It is a moot question whether the injection of extracts of at least some of the contactants will build up a resistance to them This is particularly important in poison ivy Although experimentally

appears after twenty four to thirty six hours There may be years between attacks or edematous areas may appear almost daily for years In rare cases there is a periodic *recurrence of attacks Involvement of the* genitals has caused urethral occlusion Visceral involvement much more common in the hereditary form may cause death by edema of the glottis Gastro intestinal crises with vomiting and abdominal pain have occurred in many familial cases Cases simu*lating acute ileus* ruptured tubal pregnancy appendicitis acute cholecystitis renal colic and intussusception are on record Kennedy has described cases of angioneurotic edema of the brain Fever may occur but from available reports leukocytosis seems to be rare

Associated skin lesions not infrequently observed are urticaria erythema multiforme, and purpura

Prognosis—In the hereditary form the danger of death from edema of the glottis is serious Of the 170 patients cited by Bulloch 21 1 per cent died in this way and 67 9 per cent of all the deaths were due to this lesion In the nonhereditary form the prognosis is much better Spontaneous cessation after a few months or a few years is to be expected Edema of the glottis is rare in this group

Treatment—Except in the small percentage of cases in which a specific allergy is found to be responsible for the occurrence of the swellings treatment accomplishes little or nothing In such patients elimination of the offending substance from the diet may prevent recurrences Osler s statement that 'treatment is very unsatisfactory is still valid Such nonspecific measures as administration of peptone *calcium lactate* or chloride or autogenous defibrinated blood and a variety of dietary restrictions have also been found ineffective Epinephrine and cold applications may be temporarily beneficial Ephedrine (0 025 to 0 05 Gm three times a day by mouth) has been found in some cases *to lessen the severity of* or even to abolish the symptoms tracheotomy may be required for edema of the larynx in the hereditary form A concurrent acute infection often causes a temporary disappearance of the swellings A therapeutic procedure which is sometimes effective is to restrict the diet *to one* or two simple foods such as rice and milk for ten days or two weeks The swellings may cease when the number of foods is thus limited If one article of food is then added at a time each three or four days after the previous addition, it may be possible to observe that when a certain food is given the swellings reappear and that when it is withdrawn the swellings disappear In some patients it is possible to discover by this method the offending food and to prevent recurrence of the swellings by its elimination from the diet Such treatment is however by no means always successful Histaminase is usually ineffective

CONTACT DERMATITIS

Definition—Contact dermatitis is a common expression of allergy wherein an eczematous lesion of the skin appears after repeated contact with specific agents

Etiology—The two factors responsible *for the production of contact* dermatitis are (*a*) the nature of the offending agent (contactant) and (*b*) the responsiveness of the skin

Contactants—These vary from *simple* chemical substances to complex biological products Although strong chemicals applied to the skin may cause irritation the specific agents responsible for contact dermatitis are usually not irritating when first applied to normal skin Those which penetrate *the horny layer of the skin* most readily to reach the underlying epidermis are as a rule encountered most frequently Thus common contactants are plant oils

DISEASES DUE TO PHYSICAL AGENTS

AVIATION MEDICINE

Aviation medicine is that branch of medicine which deals with the health of the personnel engaged in the practice of flying civil and military aircraft. Owing to advances in the performance of the airplane at progressively higher altitudes and speeds the aviator has been exposed to hazards that *are characteristically different from those of* the worker and the military man on the ground. An understanding of the physiology of man under conditions of decreased barometric pressure is essential to the medical care of the aviator. As in industrial medicine generally preventive treatment assumes a predominant role.

The Selection of Aviators and Health Maintenance.—The selection of candidates for flying is one of the important duties of the flight surgeon. He must decide whether the man is fit to operate a plane in which not only his own health but that of passengers or the other members of the crew is involved. The physical examination is conducted with special care to determine the presence of those physical defects which would prevent the full efficiency of the aviator at altitude. This includes special consideration of the heart, eyes, ears, accessory sinuses and the central nervous system. The psychiatric examination is aimed to exclude the *unsafe* flyer, namely the psychoneurotic, the psychotic and unstable personalities. Special tests of physiological and mental functioning have been employed to determine the candidate's reaction to low barometric pressure; one procedure of this nature consists of observation of the impairment in emotional control which takes place as a result of altitude anoxia.

The maintenance of the health of airforce personnel, both the aviator and the ground crew, has become a complex problem. It must be steadily borne in mind that any illness, physical or mental, is not a personal problem but one that involves the lives of many others. Since the aviator may travel to all parts of the globe he is immunized with typhoid, tetanus and diphtheria vaccines and against other diseases to which he may be exposed or for which adequate vaccines are afforded. The seriousness of the venereal disease problem in civil and military aviation requires intelligent handling without the raising of a moral issue. Since *sulfadiazine therapy has demonstrated its* effectiveness in gonorrhea and its relative freedom from toxicity, this situation may now be dealt with in a far more favorable way than previously.

The employment of vitamins, especially A, C and the members of the B complex, may be of value in maintaining a high degree of fitness. In night flying it is evident that deficiency of vitamin A should be guarded against.

Use of military aircraft at temperatures which vary from minus 60° F in Canada and Alaska to 120° F in tropical countries has given the physician the responsibility of protecting the aviator against both undue heat and cold. With the spread of airplane travel after the war it is likely that many of the hazards which are now a daily occurrence in military aviation will be present to a varying degree in civil aviation.

Other threats to the health of the aviator include noise, vibration, aero embolism, air sickness, acute altitude sickness, fatigue states and the effects of acceleration such as blackout.

Acute Altitude Sickness.—Acute altitude sickness is a clinical disorder with characteristic symptomatology due to anoxia during high altitude flight. The term suggested by Schneider and used by Armstrong is adopted here since it distinguishes the condition from mountain sickness, which refers to the effect of continuous anoxia in mountainous regions. Since intermittent exposure to altitude anoxia in an airplane is not followed by acclimatization, it is important to treat this condition as a separate entity.

such prophylactic or phylactic treatment does not seem valid clinically there are many favorable reports The only certain cure is the discovery of the offending allergen and its avoidance

The principles of local treatment are important since drugs applied repeatedly to excoriated skin may cause a superimposed contact dermatitis on one for which treatment is sought Wet dressings of saturated solution of boric acid or 5 per cent aluminium acetate for the acute stage followed by a bland grease such as 3 per cent boric acid in nonallergic cold cream will often allay itching provided the contactant has been removed There is always danger of overtreatment and in severe stubborn cases hospitalization where the patient can be protected and nursed is recommended

is below 85 per cent a rise in cardiac output takes place

Other effects of acute anoxia such as that on the adrenal gland the blood sugar and other blood constituents are now under intensive investigation

Symptoms—The symptoms of acute altitude sickness are characteristic varying with the degree of anoxia At an altitude of 12 000 feet there is in addition to the slight increase in breathing and elevation of the pulse rate a gradual onset of headache and lassitude especially if the exposure is longer than two or three hours An euphoric state manifested by overconfidence and undue hilarity takes place in about half the people exposed to anoxia in the others a depressed or sleepy tendency is noted At an altitude of 15 000 feet these symptoms are more pronounced and nausea and vertigo may develop At 18 000 feet about 25 per cent of normal individuals collapse in a period of one half to one hour Vomiting with severe headache may occur with more prolonged exposure to altitudes between 12 000 and 15 000 feet In certain persons the disturbance in mental function is completely unrecognized and unfortunately accompanied by such impairment in emotional control as to lead to seriously disturbed judgment The character of the mental disturbance is comparable to that produced by alcoholism As a result it has become difficult to convince pilots and others of the deleterious effect of altitude anoxia on the central nervous system and of the danger of flight while suffering from it

The effect of altitudes of 10 000 to 15 000 feet on the circulatory system is shown by an increase in pulse rate and a gradual though slight rise in systolic pressure The electrocardiogram reveals a characteristic depression in the height of the T wave When collapse takes place at an 18 000 foot altitude it is generally due to a peripheral circulatory failure characterized by a fall in blood pressure

Many tests of the special senses have been made to determine the effect of moderate anoxia on these functions By the use of angioscotometry an increase in the size of the blind spot has been conclusively demonstrated above a 10 000 foot altitude Dark adaptation and accommodative power are impaired at altitudes of 12 000 to 15 000 feet and above with decreasing visual acuity and light perception Neuromuscular control is diminished after exposure of one to two hours to altitudes of 12 000 and above Tactile sensation and hearing however are not generally affected until altitudes as high as 16 000 to 18 000 feet are reached

Prognosis—The effect of altitude anoxia such as is generally encountered in flight is temporary disappearing in a few hours or a few days depending upon the degree and length of exposure to oxygen want

Fatigue is one of the most common after effects of prolonged anoxia in aviators subjected to intermittent exposure to high altitude A fatigue state of a more chronic character sometimes takes place In most cases a long rest period is sufficient to overcome the condition In a few instances however a clinical disorder called 'aero neurosis by Armstrong develops as a result of the accumulative effects of repeated anoxia and the unusual hazards and responsibilities involved in flying This clinical entity is characterized by bodily and mental fatigue nervousness lassitude irritability and frequently by gastro intestinal disturbances

Treatment—Prevention of altitude anoxia seems the most rational approach to the treatment of this syndrome Since it has been adequately shown that oxygen want at moderate altitudes may produce sharp impairment in emotional control with a resultant potentially serious disturbance in judgment it is the responsibility of those in charge of civil and military aviation to use adequate oxygen inhalation for all members of the crew at altitudes above 10 000 feet and at lower altitudes in which prolonged flight takes place This point of view is additionally supported by the development in a limited number of aviators of chronic fatigue in which repeated exposure to anoxia may have been a factor

The oxygen apparatus employed has been in some instances a tube held within the mouth the so-called pipestem method Although it is effective at lower altitudes its disadvantage lies in the considerable variation in the concentration of oxygen inhaled and the ease with which the oxygen tube may be put aside Mask oxygen appa

Etiology—Swift ascent in an airplane to increased altitude brings the pilot and passengers to atmospheres in which the barometric pressure is progressively decreased This results in a lowered partial pressure of oxygen in the lungs with a consequent diminished pressure of oxygen in the arterial blood and in the tissues a condition called "acute anoxia'

Morbid Anatomy—Flight at moderate altitudes such as 5000 to 15 000 feet is followed by physiologic changes without demonstrable damage to the organs of the healthy individual This is also true of flight at altitudes between 35 000 and 44 000 feet when pure oxygen is breathed, leaving out of consideration the development of aero embolism The pathologic changes caused by severe oxygen want which may occur at very high altitudes on failure of the oxygen supply are those of asphyxia These consist of dilatation of the capillaries with increased

TABLF I

permeability hemorrhage edema and perivascular infiltration Both small and large hemorrhages occur and affect the nerve cells in the cortex of the brain as well as the corpus striatum and medulla Hemorrhages also take place in the heart muscle mitral valve lungs kidneys and other organs

Pathologic Physiology—As the airplane ascends to increased altitude the most significant effect of the lowered barometric pressure is a progressive decrease in the partial pressure of oxygen in the lungs The inhalation of 100 per cent oxygen may compensate for the diminished alveolar oxygen pressure up to altitudes of 34 500 feet When an altitude of 42 000 feet is reached even during the inhalation of pure oxygen the oxygen saturation of the arterial blood is comparable to that found in a person without oxygen at an altitude of 14 500 feet (See Table I) The composition of air at these altitudes in terms of the concentration of oxygen carbon dioxide nitrogen, and the rare gases is the same but the pressure of oxygen in the lungs is characteristically lowered

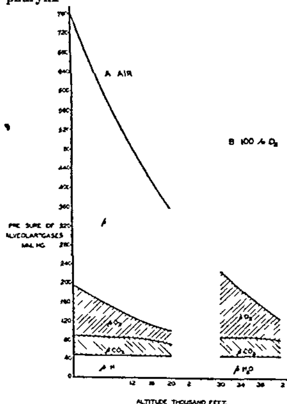
Thus at an altitude of 12 000 feet the barometric pressure has fallen from 760 mm. to 483 mm of mercury The pressure of oxygen in the atmosphere may be calculated by multiplying 483 by 0 209 the percentage of oxygen in the air at any known altitude When the atmosphere is inhaled it is saturated in the lungs with water at a body temperature of 37° C resulting in a water vapor pressure of 47 mm of mercury The alveolar air in the lungs has a relatively constant pressure of carbon dioxide about 40 mm of mercury The actual pressure of oxygen on the capillaries of the lungs is therefore materially less than the fall in total barometric pressure would indicate which is a factor of considerable importance in calculating anoxia at high altitudes Thus, the alveolar oxygen pressure may be obtained through the following equation

$$[(483-47)\times 0\ 209]=40 \text{ or } 50 \text{ mm Hg}$$

instead of the sea level alveolar oxygen pressure of 108 mm Hg which may also be calculated by the above formula

This lowered pressure of oxygen in the lungs is insufficient to oxygenate completely the hemoglobin in the red corpuscles which results in an oxygen saturation of the arterial blood of approximately 85 per cent The tissues, which are thus in contact with a lowered oxygen tension respond with a varied symptomatology depending on the degree to which the various organs are impaired by anoxia The higher centers of the brain are most sensitive to oxygen want the heart next and perhaps the adrenal glands third but bone and muscle tissue are relatively much less affected

Stimulation of breathing is noticeable above 8000 feet and is more marked at 12 000 to 15 000 feet As a result of the increased volume of ventilation an increased proportion of carbon dioxide is eliminated from the lungs With the slight fall of carbon dioxide pressure there is a shift of the acid base equilibrium toward the alkaline side When an altitude is reached in which the oxygen saturation of the arterial blood



cury at pressures over 15 mm the discomfort is increased and frequently accompanied by tinnitus and actual pain The symptoms referable to the middle ear are more common as a cause of occupational disability and of passenger discomfort than all other complaints referable to air travel In some persons failure to obtain an equalized pressure on both sides of the drum may be followed by vertigo and deafness Inspection of the drum may reveal a moderate degree of redness

A chronic form of this condition takes place in which the ear drum is retracted and the drum membrane dull and thickened The patient complains of a full and stuffy feeling in his ears and of head noises Occasionally vertigo is present

Other effects of airplane travel on the ear are the noise and inevitable vibration which are more apt to affect the hearing than pressure changes in the middle ear

Treatment —Swallowing is the most common method of equalizing the pressure in the middle ear by opening the eustachian tube Chewing gum is helpful by creating a greater flow of saliva In many instances however the symptoms persist after swallowing It is then advisable to yawn repeatedly with the mouth as widely open as possible until the feeling of pressure disappears Sometimes it is necessary to hold the nose tightly and blow out with mouth closed in order to force air into the eustachian tube In rare instances if an equalization has not taken place and pain continues reascent to the higher level where pain first occurred and then gradual descent after pressure has become again equalized may afford relief The inhalation of helium-oxygen mixtures during or after descent may result in relief of pain since the smaller helium molecules may diffuse into the eustachian tube more readily than nitrogen Active treatment consists in inflating the tympanum by Politzer s method The instillation of copious quantities of water at a temperature of 110° F followed by dry heat is apt to relieve pain

Since pressure effects on the ears vary with the rate of ascent and descent the airplane companies have generally limited themselves to 300 feet per minute. Unforeseen conditions however may require that these rates be exceeded to ensure safety of the flight Both in military operations and in chamber experiments rates of ascent and descent of 3000 to 5000 feet per minute are generally well tolerated by persons who have no acute or chronic illness in the nose and pharynx

(A) Breathing air (B) Breathing 100% oxygen

Fig 46.—Fall in partial pressure of oxygen and carbon dioxide in the lungs at increasing altitudes A During ascent to an altitude of 20 000 feet there is a progressive fall in the pressure of nitrogen and oxygen in the alveolar air whereas the carbon dioxide pressure is only slightly lowered and the pressure of water vapor remains constant.

B Although 100% oxygen is breathed during ascent from 30 000 to 4 000 feet alveolar O is reduced to that which occurs in a subject breathing air at 14,500 feet The sum of water vapor and CO_2 pressure 83 mm Hg, constitutes at an altitude of 42 000 feet a far larger proportion of the total barometric pressure, 128 mm Hg than at the lower altitudes Thus the necessitous evolution of carbon dioxide and water vapor from the lungs limit more and more the quantity of oxygen that can be inhaled as progressively higher altitudes are reached

Aero embolism —Aero embolism is a clinical disorder due to formation of nitrogen bubbles in the blood and tissues of the body as a result of swift ascent to altitudes above 18 000 feet It is characterized by symptoms referable to the organ involved, most frequently by pains in the joints

ratus is more effective and may also be employed to administer 100 per cent oxygen Of these the *B L B mask is comfortable* and efficient employing a bag which allows a small amount of rebreathing and a sponge rubber disk which functions as a combined inspiratory and expiratory valve The Meter mask is equally comfortable and efficient but employs a collecting bag without rebreathing Delicate inspiratory and expiratory valves are responsible for minimal resistance in this mask an injector makes it possible to administer any oxygen concentration desired These masks operate on a constant flow of oxygen into the system which can be changed depending on the altitude reached The military services both here and abroad have devised special mask oxygen apparatus which function on a demand type of regulator in which a slight fall of pressure in the mask allows the entrance of sufficient oxygen for inspiration With the rise in pressure in the mask during expiration the inflow of oxygen is stopped at the regulator

There is no indication for the use of carbon dioxide in the treatment of altitude anoxia At low or moderate altitudes inhalation of oxygen enriched atmospheres prevents anoxia and its consequences such as hyperventilation and alkalosis At altitudes of 37 000 to 42 000 feet inhalation of pure oxygen is indicated since addition of carbon dioxide could only be made at the expense of a lowered oxygen pressure Due to the relative expansion of gases as the barometric pressure is lowered 2 per cent carbon dioxide at sea level would become over 15 per cent carbon dioxide at a 40 000 foot altitude Addition of this percentage of carbon dioxide would lower the oxygen in the inspired air from 100 per cent to 85 per cent evidence has been obtained that there is no value in replacing 10 per cent oxygen with 10 per cent carbon dioxide at these high altitudes

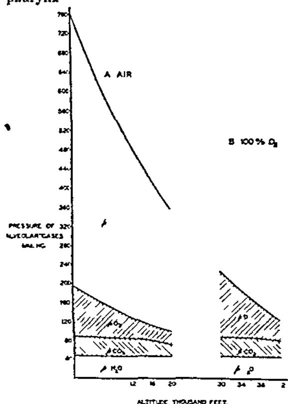
The actual treatment of persons previously exposed to altitude anoxia is return to a sea level atmosphere In patients who have been transported by airplane such as those suffering from cardiac or respiratory disease additional measures may be required The patient with coronary artery disease should not fly at altitudes of 10 000 feet or over without continuous inhalation of oxygen since there is evidence that this degree of anoxia may result in spasm of the coronary arteries and perhaps in thrombosis

Patients with pulmonary fibrosis and emphysema may suffer from serious dyspnea unless they inhale oxygen continuously when flying The physical expansion of gases at altitude may be responsible for distress in cases of therapeutic pneumothorax This applies also to patients with appendicitis or other lesions in the gastro intestinal tract in which expansion of the intestinal gas might result in perforation

Aero otitis Media —Aero otitis media is the term employed by Armstrong and Heim to describe acute and chronic traumatic inflammation in the middle ear caused by pressure differences in the tympanic cavity and that of the surrounding atmosphere As a result of similar changes of altitude in airplane flights, inflammation in the frontal and maxillary sinuses may also take place

Etiology —During ascent to high altitude the air in the eustachian tube is under increased pressure until the flapper like valve in the pharynx opens During descent a negative pressure exists in the eustachian tube until air has been admitted through its pharyngeal opening Inability to open the eustachian tube during changes in altitude may expose the middle ear to abnormally increased or decreased pressures and result in acute or chronic inflammation. In acute upper respiratory infection the opening into the eustachian tube or any of the accessory sinuses may be partially or completely closed by swelling of the mucous membrane Less disturbance is apt to be produced during ascent since the increased pressure of air in the eustachian tube and in the sinuses generally forces its way through even partially closed openings However during descent the flapper valve at the pharyngeal entrance to the eustachian tube may fold inward and effectually prevent the equalization of pressure Atmospheric pressure on the external surface of the middle ear becomes progressively greater than the pressure still existing on its inner surface If unrelieved hemorrhage and rupture of the drum may take place

Symptoms —A feeling of fulness in the middle ear is perceptible in most individuals at pressure changes of 3 to 5 mm of mer



cury at pressures over 15 mm the discomfort is increased and frequently accompanied by tinnitus and actual pain The symptoms referable to the middle ear are more common as a cause of occupational disability and of passenger discomfort than all other complaints referable to air travel In some persons failure to obtain an equalized pressure on both sides of the drum may be followed by vertigo and deafness Inspection of the drum may reveal a moderate degree of redness

A chronic form of this condition takes place in which the ear drum is retracted and the drum membrane dull and thickened The patient complains of a full and stuffy feeling in his ears and of head noises Occasionally vertigo is present

Other effects of airplane travel on the ear are the noise and inevitable vibration which are more apt to affect the hearing than pressure changes in the middle ear

Treatment —Swallowing is the most common method of equalizing the pressure in the middle ear by opening the eustachian tube Chewing gum is helpful by creating a greater flow of saliva In many instances however the symptoms persist after swallowing It is then advisable to yawn repeatedly with the mouth as widely open as possible until the feeling of pressure disappears Sometimes it is necessary to hold the nose tightly and blow out with mouth closed in order to force air into the eustachian tube In rare instances if an equalization has not taken place and pain continues reascent to the higher level where pain first occurred and then gradual descent after pressure has become again equalized may afford relief The inhalation of helium-oxygen mixtures during or after descent may result in relief of pain since the smaller helium molecules may diffuse into the eustachian tube more readily than nitrogen Active treatment consists in inflating the tympanum by Politzer s method The instillation of copious quantities of water at a temperature of 110° F followed by dry heat is apt to relieve pain

Since pressure effects on the ears vary with the rate of ascent and descent the airplane companies have generally limited themselves to 300 feet per minute Unforeseen conditions however may require that these rates be exceeded to ensure safety of the flight. Both in military operations and in chamber experiments rates of ascent and descent of 3000 to 5000 feet per minute are generally well tolerated by persons who have no acute or chronic illness in the nose and pharynx

(A) Breathing air (B) Breathing 100% oxygen

Fig 46—Fall in partial pressure of oxygen and carbon dioxide in the lungs at increasing altitudes A During ascent to an altitude of 20 000 feet there is a progressive fall in the pressure of nitrogen and oxygen in the alveolar air whereas the carbon dioxide pressure is only slightly lowered and the pressure of water vapor remains constant.

B Although 100% oxygen is breathed during ascent from 30 000 to 42 000 feet alveolar O is reduced to that which occurs in a subject breathing air at 14,500 feet. The sum of water vapor and CO_2 pressure 83 mm Hg constitutes at an altitude of 42 000 feet a far larger proportion of the total barometric pressure 128 mm Hg than at the lower altitudes Thus the necessitous evolution of carbon dioxide and water vapor from the lungs limit more and more the quantity of oxygen that can be inhaled as progressively higher altitudes are reached

Aero embolism —Aero embolism is a clinical disorder due to formation of nitrogen bubbles in the blood and tissues of the body as a result of swift ascent to altitudes above 18 000 feet It is characterized by symptoms referable to the organ involved most frequently by pains in the joints

Etiology—The abrupt fall in atmospheric pressure which produces the elimination of free gases in the blood has been carefully studied in deep sea divers as caisson disease and by others at high altitude especially Armstrong who employed the term aero embolism to describe the condition All of the tissues of the body are saturated with nitrogen at sea level body fats dissolve six times as much nitrogen per unit mass as does the blood itself With rapidly decreasing atmospheric pressures gas bubbles may theoretically be formed at one half an atmosphere 18 000 feet altitude but are not common below 27 000 feet equivalent to one third an atmosphere The symptoms of aero embolism are apt to take place in most subjects unless special means of prevention are undertaken

Pathological Physiology—At sea level pressure 100 cc of blood dissolves 1.5 cc nitrogen 0 25 cc oxygen and 0 83 cc carbon dioxide although larger amounts of oxygen and carbon dioxide are carried in loose chemical combination The pressure of carbon dioxide in the body is governed by the alveolar carbon dioxide pressure which is an approximately constant pressure of 40 mm of mercury in the healthy state The oxygen pressure in the tissues even during the inhalation of 100 per cent oxygen at sea level never rises to high levels since 5 to 6 cc of oxygen in 100 cc of blood are consumed by the tissues The oxygen pressure in venous return blood is probably therefore, never higher than 50 mm of mercury However nitrogen is physiologically inert and goes into simple solution in the body fluids in an amount dependent on the partial pressure of nitrogen in the lungs When the airplane makes a swift ascent to a high altitude such as 40 000 feet nitrogen at a former sea level pressure of 560 mm of mercury in the body fluids is abruptly in contact with an atmosphere in which the total pressure is 141 mm and the blood nitrogen pressure almost zero

This excessive pressure differential is responsible for the evolution of nitrogen bubbles The sea level pressure of oxygen and carbon dioxide are not sufficient to cause bubble formation but after a nitrogen bubble has been formed oxygen and carbon dioxide diffuse into it according to their relative partial pressures

Symptoms—The symptoms depend on the number, size, and location of the bubbles The most frequent complaint is pain around one or more of the joints which represent an embolus in the bone periosteum or tendinous connections about the joint At first it feels like an ache but swiftly grows worse and in fifteen minutes may become intolerable Other frequent symptoms are itching in the skin with at times urticarial lesions In about 6 per cent of the cases the lungs are the cause of severe symptoms Gas emboli picked up from the tissues by the venous blood end in the pulmonary arterioles and capillaries The patient complains of burning pain followed by prolonged coughing spells Edema of the lungs develops quickly and descent to sea level is necessary to get rid of the edematous fluid in the alveoli by effective coughing

The most serious location for embolism is the central nervous system A few cases of such involvement have been described in which paralysis unconsciousness and convulsions occurred In all these instances there was prompt recovery without any permanent after effects after the subjects were brought to sea level pressure Although increase in spinal fluid pressure has been reported recent investigations have indicated that the pressure in the spinal fluid is not definitely affected by lowering of the barometric pressure

Treatment—Prevention of aero embolism should be carried out whenever possible In commercial flying an altitude of 18 000 feet should not be exceeded unless a sealed pressure cabin is used On military missions when higher altitudes are necessary several procedures are employed Since it has been known that certain individuals are less apt to develop aero embolism than others preliminary tests in a low pressure chamber are utilized to select those aviators who are less likely to develop the condition

A more reliable method is to allow the aviator to inhale pure oxygen for a period of one to three hours before ascent to high altitude The inhalation of oxygen results in a progressive diffusion of nitrogen through the lungs In five hours approximately 95 per cent of the dissolved nitrogen is elim

inated from the body Exercise both active and passive, increases the cardiac output and the elimination of nitrogen

Since there is no reliable method of knowing whether a man will consistently be free of aero embolism at altitudes above 30 000 feet nitrogen desaturation by inhalation of pure oxygen should be used wherever possible for a period of two or preferably three hours This is especially important in airplanes where large crews are operating in which development of the symptoms in one member may necessitate abandonment of the mission Although aero embolism is confined to the military air services it must be remembered that sealed cabin planes were already operating in commercial transports before the war It is very probable that pressure cabin flying will undergo a swift development after the war because of greater speed and comfort in traveling At altitudes above 20 000 feet a leak in the pressure cabin with sudden fall in pressure may cause symptoms of aero embolism in some of the passengers

Effect of Accelerations on the Body — The effect of acceleration on the body is most commonly seen in the so called 'black out' in which a flyer pulls out from a dive and for one to three seconds is unable to see This sudden loss of vision takes place also if a turn is made at high speed

Speed itself has no effect on the human body if it is constant in rate and direction provided the individual is protected against the blast of the wind Acceleration which may be defined as the rate of change of velocity produces sudden and profound effects on the body The military forces are intensively concerned with measures which will prevent harmful effects of acceleration and with procedures which may allow the aviator to withstand higher accelerations without blacking out both in dive bombing and in swift turns at high altitude fighting

Acceleration or a change in the velocity of the body may take place theoretically if the airplane is moving in a constant direction and the speed is suddenly either increased or decreased as for example when the brakes of the airplane are suddenly applied The second and almost the only form in which acceleration is actually produced in flight is for the speed to remain relatively constant and for the direction to suddenly change thereby subjecting the body to an abnormal force The amount of force developed in accelerations which are simply due to change in speed called *linear accelerations* are calculated from Newton's law $F = MA$ in which the force is proportional to the mass and the acceleration When the acceleration is created by a change in direction that is by centrifugal acceleration, the amount of force is calculated from the equation $F = \frac{MV_2}{r}$ in which V = velocity r the radius of the turn and M the mass

The pull of gravity which attracts us to the earth has been selected as the unit to measure the force exerted on the body during acceleration in flight This can be expressed in terms of the body's weight since it is proportional to mass In aviation medicine the symbol 'g' is employed to report the force which attracts us to the earth, thus 2 gs is twice that force and 5 gs five times that force

Although there is no difference between the effect of acceleration forces which arise from linear or centrifugal acceleration the axis of the body through which the force acts is important When the pilot is seated in the conventional manner in aircraft and pulls out from a dive or turns at a high velocity a force is exerted directly through the long axis of the body from head to foot and is termed *positive* acceleration Both the duration and the magnitude of positive acceleration determine the *degree of black out* It has been found that 7 gs cannot be maintained for more than three seconds in a pull up from a dive or 4 gs for more than five seconds

The principal effect of a force of 2 gs acting on the body is a feeling of increased weight in the limbs This is increased to a sensation of being pressed down into the seat at 3 gs and at 5 gs there is also clouding of vision as though a gray veil were in front of the eyes In the average person 5 to 6 gs will cause the symptom known as blackout a temporary loss of vision At this time the body is markedly compressed in a vertical position and the head feels as though it were being pressed into the shoulders Above 6 gs consciousness is lost if the acceleration lasts two seconds Considerable variation exists

in the extent to which acceleration can be borne, depending upon the time and on the type of individual Tall, slender men are less resistant to centrifugal force than small heavy set people and persons with high blood pressure do better than those with low blood pressure

The mechanism of blackout can be traced to the effect of high centrifugal force on the blood stream A force acting in the direction of head to foot tends to prevent blood from flowing from the foot to the head The venous return of blood to the heart is decreased and there is a force which tends to retard the flow of blood toward the head in the arterial system Added to that there is undoubtedly a sudden cessation of the flow of blood in the capillaries When the arterial blood supply to the eye falls below a certain level vision fails and soon after that the brain becomes inadequately supplied with blood and consciousness is lost The fundamental effect is that of acute anoxia which is especially harmful to the organ most sensitive to oxygen want, namely, the central nervous system

Treatment—The treatment of this condition is in the first place to select aviators who tolerate it better than others If it were possible for the crew to be placed prone in the airplane the acceleration forces set up in dive bombing would act transversely across the body without causing blackout or with a marked diminution in its severity This has not so far been found practical An inflatable abdominal belt has been found helpful though not comfortable The most practical method of reducing the effects of centrifugal force is sitting in the forward crouch position in which the trunk is tilted forward and the knees drawn upward This position decreases the distance which the blood has to be pumped vertically and the large blood vessels of the trunk are not in the direct line of acceleration It has been found that a person may tolerate an additional 2 gs if he adopts the forward crouch position

SEA SICKNESS AND AIR SICKNESS

These two conditions are in all probability due to the same causes and can be considered together Air sickness and sea sickness may be defined as conditions due to frequently repeated oscillatory movements of the body in a ship or airplane, and characterized by dizziness, nausea vomiting pallor and sweating

Etiology—In a ship the pitching seesaw movement on a transverse axis through the center of the ship the rolling movement on its long axis the movement of the entire ship up and down and the vibration occurring in most ships constitute the usual motions to which an individual is subjected In airplane travel there are vertical accelerations excessive rotary motions and vibration which bring on the disturbance Although many possible mechanisms have been described for both these conditions all the available evidence favors the belief that motion sickness is essentially due to disturbed vestibular function It is also true that visual psychogenic, and kinesthetic factors play a subsidiary role varying with the individual

Symptoms—The symptoms may come on without warning A man who was previously in good spirits may suddenly become quiet and subdued He feels nauseated and is aware of excessive salivation Mental depression is almost constantly present Vomiting may then take place with mild headache Pallor and cold sweats are common, true vertigo is rare There are no characteristic objective signs although a drop in systolic blood pressure has been reported accompanied by tachycardia or a slow pulse rate The nervous component in both air and sea sickness is at times important Some individuals will develop the condition after the briefest possible exposure It is sometimes brought on by bad odors or poor ventilation

Treatment—Fixing the eye on a definite object in space undoubtedly is of real help in both air sickness and sea sickness The eye should not be allowed to shift with the position of the airplane as the earth or sky will swim past the eyes and produce dizziness or nausea in a manner comparable to the development of this condition when one whirls rapidly on a piano stool The eye should remain fixed on an object on the ground or on the horizon

Abdominal belts and supports have been found helpful by many investigators by

reducing the movement of the heavy viscera or perhaps by preventing venous pressure changes in the abdominal veins If it is possible to lie supine in the center of the airplane or ship less disturbance is apt to be felt Many drugs have been advocated which either act as sedatives to the entire organism or effectively suppress the parasympathetic nervous system The combination of belladonna and a sedative drug has much to support it In the latter category sodium amytal and phenobarbital are most highly thought of Any drug which would cause dilatation of the pupils or reduce efficiency by sedation would be questioned by the military forces However the use of moderate doses of these drugs might be preferable even in combat to the incapacity which severe motion sickness induces

In sea sickness the judicious and even injudicious use of alcohol has been given a high place as a therapeutic agent both by professional and lay observers

COMPRESSED AIR ILLNESS

(Caisson Disease The Bends Divers Palsy)

Compressed air illness is produced in individuals who after having breathed air under a pressure of considerably more than 1 atmosphere are subjected to unduly rapid reduction of air pressure The disease was described in 1841 by Triger a French engineer who first employed a caisson in 1839 With the great increase in the use of compressed air in deep water diving and in such engineering operations as pier construction and tunneling numerous opportunities for the development of the malady occur

Etiology —Workers entering a caisson pass through an airlock or chamber where the pressure is elevated to that of the working space On leaving the caisson decompression is also effected in the airlock If the change takes place too rapidly the atmospheric nitrogen dissolved in the body under pressure is liberated as nitrogen bubbles which when sufficiently profuse obstruct the circulation It has been assumed that these bubbles in nerve tissue fat tendon sheaths fascia intestinal mucosa and throughout the body give rise to caisson disease However recent studies conducted by Behnke and his associates indicate that gas bubbles to which symptoms could be attributed were observed only in blood vessels and it is believed by these investigators that the etiology of bends is essentially the result of embolic ischemia of osseous tissue

There is little or no danger in rapid decompression from working pressures of 15 pounds* or less. At pressures above this however caution must be exercised to avoid overexposure of workers and unduly rapid decompression. Although various methods and rates of decompression have been proposed no one schedule at the present time is universally used. Rules and regulations governing work in compressed air have been adopted by the U S Navy Department and by legislation in some states. The uniform method of decompression is favored in some regulations and the interrupted or stage method in others. The relative merits of the two methods remain to be determined.

The use of oxygen instead of air during the later stages of decompression has been demonstrated as effective in materially reducing the time of decompression.

Experimental work with respirable mixtures of helium and oxygen used as substitutes for normal air has shown that helium is about half as soluble as nitrogen in body tissues is more rapidly diffused, and that the use of helium oxygen mixtures permits of more rapid decompression than is possible after exposure to compressed air.

Cases of collapse have occurred in submarine escape training with the Momsen lung used in the United States Navy. Most have developed in ascents from depths of less than 5 fathoms (equivalent to less than 15 pounds gauge pressure) and cannot be attributed to caisson disease. Polak and Adams have recently ascribed the cause of collapse or death in these cases to air embolism.

Symptoms—The more important evidences of compressed air illness in order of frequency are (1) localized pain in one or more extremities or in the abdomen ("the bends") which is the only symptom in about 90 per cent of the cases (2) vertigo ("staggers") which occurs alone or with other symptoms (3) involvement of the central nervous system monoplegia or diplegia due to cerebral irritation or sensory and motor disturbances attributable to the presence of gas bubbles in the spinal cord (4) cutaneous manifestations ("itch") (5) asphyxia ("the chokes") and (6) collapse and unconsciousness. Characteristic bone changes appearing in caisson workers have been demonstrated by x ray examination. The onset of symptoms in about 50 per cent of the cases occurs within thirty minutes after decompression in 90 to 95 per cent within three hours.

Prognosis—If promptly and properly treated the chances of complete recovery are excellent. Cases untreated for several hours after the onset of symptoms are not so favored. Recovery after collapse is doubtful.

Compression Effects—During rapid compression violent pain in the ear ("ear block"), and even rupture of the tympanum may occur because of difference in pressure on the two sides of the tympanic membrane. Similarly air under pressure may become trapped in the sinus ("sinus block") causing acute pain. Infections of the upper respiratory passages may partially obstruct the aural and sinal spaces and thus cause a difference in pressure between adjacent spaces resulting in congestion edema and hemorrhage. Impaired hearing vertigo and autophony may be caused by hemorrhage into the middle ear and vestibule.

Other compression effects result from the constituent gases of the air. At high pressures oxygen may cause convulsive seizures which may attack the worker with little warning. Nitrogen absorbed under high pressure exerts a narcotic effect on the subject and impairs his ability to perform mental tasks. The effect can be minimized or abolished by the substitution of helium for nitrogen. The partial pressure of carbon dioxide at a depth of 200 feet rises to about 7 per cent of an atmosphere. Such a high concentration may cause unconsciousness in some workers after a short exposure.

Treatment—Treatment of caisson disease is essentially recompression and subsequent slow decompression. No standardized method has been adopted. A procedure recently recommended is to place the subject at the earliest possible moment after the onset of symptoms in a steel chamber or "medical lock" where pressure is applied until all symptoms are relieved and in addition to add 1 more atmosphere in the effort to completely restore blood supply to the affected tissues. The patient is subjected

* A working or gauge pressure of 15 pounds represents pressure above that of a single atmosphere

to this pressure for a minimum of thirty minutes, then the pressure is reduced to 30 pound gauge and oxygen is substituted for air which the patient breathes for one and a half hours during which period the return to normal pressure proceeds Unrelieved symptoms require a prolonged stay (overnight soak) at a pressure of 30 pounds or under for a period of twelve to twenty four hours followed by a gradual decompression to atmospheric pressure

MOUNTAIN SICKNESS

The ascent to high altitudes of persons accustomed to life under the pressure of practically one atmosphere (760 mm mercury) may produce distressing and possibly serious consequences The effects of diminished pressure may be manifested quickly if the ascent be rapid as in aeroplanes or balloons or more gradually during mountain climbing These are produced not by the reduction of mechanical pressure but result from the diminished partial pressure of oxygen In individuals permanently resident in rarefied air there are structural and functional adaptive changes Few persons escape slight discomfort at least on ascending more than 12 000 feet above sea level

The principal factors in acclimatization are (a) increased volume of air breathed (b) increased alveolar oxygen pressure (c) increase in red cells in proportion to the increase in hemoglobin (d) increase in size of red cells (e) increase in viscosity of the blood and in resistance to hemolysis (f) increase in serum proteins (g) diminution in available alkali (h) decreased alveolar carbon dioxide (i) decrease in arterial oxygen saturation At high altitudes new formation of red cells has been indicated by the large percentage of reticulated cells in the blood Hurtado found an increase in the mid capacity of the lungs a true physiologic emphysema and augmented vital capacity

Symptoms of mountain sickness differ in kind and severity in different individuals and at different altitudes In mountain climbing the effects of diminished pressure may be observed at much lower altitudes than in aviation because of the association of rarefied air and more or less severe physical exertion Individuals suffering from cardiovascular disease are of course at a peculiar disadvantage and in them the effects of a rarefied atmosphere are correspondingly intensified Frontal headache vertigo malaise mental dulness abnormalities of vision and hearing epistaxis nausea vomiting thirst cyanosis dyspnea palpitation and muscular weakness are commonly noted There may be slight fever The pulse is accelerated and the systolic blood pressure moderately raised With rest some degree of accommodation is ordinarily acquired within a few days Oxygen affords prompt relief

The effects upon aviators of rapid ascent and descent are of a somewhat different character Few symptoms are noted on ascending short of 12 000 feet Dyspnea is then common and as the altitude is increased headache muscular weakness apathy and psychic disorders may be manifested At an altitude of 20 000 feet fliers are in danger of collapse without oxygen supply With oxygen equipment they can climb to 40 000 feet without serious effects but at altitudes much beyond this symptoms of anoxia must be expected even when pure oxygen is breathed

Aside from the effects of low barometric pressure flying personnel engaged in military operations encounter many additional hazards Important among these are aero embolism ("altitude bends") a condition analogous to compressed air illness effects of vibration noise and of speed the most dangerous of which is transient blindness (blacking out) and unconsciousness resulting from sudden change of direction severe stresses and strains from low temperatures effects of pressure variations in the auditory canals and paranasal sinus passages, pilot fatigue and psychological tension and loss of sleep

Treatment —To relieve oxygen want in mountain sickness, oxygen should be given Discussions on methods of protection of flying personnel against the many hazards that are encountered and the treatment of affections following exposure to these hazards can be found in the chapter on aviation medicine (p 495)

HEAT EXHAUSTION AND HEAT STROKE

Exposure to high heat particularly when it is associated with high humidity may result in quite diverse effects varying from the superficial manifestations of radiant heat to heat cramps heat exhaustion heat stroke (heat hyperpyrexia thermic fever), or sudden death

Heat exhaustion is characterized by pronounced weakness dizziness stupor pallor profuse perspiration diminution of urine, acceleration of the pulse rate and of respiration, and a lowering of blood pressure. There is rarely loss of consciousness Occasionally cramping pain in the muscles of the abdomen or extremities may be noted The mouth temperature may be subnormal or slightly elevated Morton with an extensive tropical experience states that the rectal temperature is invariably raised, usually to 101° F The apparent onset is usually sudden and not necessarily associated with exertion Under conditions of sustained heat, as in the tropics there may be during several days prodromal headache anorexia constipation and muscular weakness The death rate from heat in the United States according to Shattuck who collected records for a thirty three year period (1900-1932) amounted to 0 39 per 100 000 He found that deaths from heat closely correlated with unusually high atmospheric temperatures continuing for several days and are far more common in men than in women Air conditioning particularly dehumidification and cooling during the hot months offers a practical means applicable in many instances of mitigating the heat hazard indoors

In heat stroke or sunstroke the heat regulating mechanism of the body is seemingly overwhelmed and not merely embarrassed as in heat exhaustion In typical cases heat exhaustion and heat stroke are readily differentiated but there is no clear line of demarcation between the two conditions and cases of heat exhaustion may develop evidences of heat stroke The onset of heat stroke may occur with catastrophic suddenness and death be almost instantaneous or there may be premonitory headache dizziness nausea or visual disturbance Consciousness is lost early in the attack The face is flushed the skin dry and hot The temperature is elevated in the more severe cases to 109° F or more In the early stages of heat stroke the pulse is full and rapid, the breathing deep and the pupils possibly dilated As the patient's condition becomes progressively worse the pulse grows irregular rapid and more feeble the breathing more shallow and of the Cheyne-Stokes type Death may occur within a few minutes but if the patient survives the second day, re-

covery is probable Persistent susceptibility to heat and impairment of memory are commonly noted after severe attacks of heat exhaustion and heat stroke Hemiplegia and paraplegias are not uncommon sequels Signs of a damaged myocardium in the electrocardiogram immediately after heat stroke have been reported by Metz who recommends that in every case an electrocardiogram especially with functional trial should be made The predominant pathologic manifestation in the brain is edema followed by petechial hemorrhages A rather extensive hemorrhage under the endocardium of the left ventricle was noted in four fatal cases examined by Wilson who believes this to be probably the actual cause of death

Morton found in cases of heat stroke an increase of blood lactic acid and a lowering of plasma CO_2 After twenty-four hours the blood urea was markedly increased and blood and urinary chlorides reduced Hall and Wakefield observed in dogs which had reacted with the clinical picture of heat exhaustion or heat stroke renal damage with high nonprotein nitrogen a marked decrease in the alkali reserve in all cases very high blood lactic acid commonly an increase in blood chlorides and the blood sugar and total nitrogen not notably changed The serum *p*H was decreased in all cases and in organic phosphorus and serum calcium slightly increased

Heat cramps occurring in persons exposed to high heat studied in 1892 by Cronin and others have in recent years occasioned many investigations and reports The condition is found particularly among stokers miners steelworkers and others subject to intense heat and profuse perspiration The onset is usually sudden Spasms involve successively groups of muscles of the extremities or of the abdominal wall and may occur intermittently for twenty four hours seldom longer Heat cramps are now attributed to dehydration and the loss of blood chlorides This loss may amount to 20 Gm or more daily The intake of large quantities of water results in the muscular spasms a circumstance probably related to diffusion effects It is wholly possible that in some cases the cramps are due to the retention in the blood of toxic elements particularly in view of the prompt beneficial effects of the intravenous injection of sodium bicarbonate

Treatment *of heat exhaustion* usually calls only for rest in a cool place Purgation may be indicated In severe cases stimulation may be required to offset the depression and cooling sponges or warm baths to favor return of the temperature to normal Morton advocates 1 drachm of glucose and 15 grains of sodium bicarbonate to 1 ounce of water hourly for twenty four hours and in severe cases particularly those with muscular spasm 1 to 1½ pints of 2 per cent sodium bicarbonate solution intravenously

Heat stroke demands prompt and often heroic treatment Icewater baths cold sprays ice packs and ice-water enemata may be used until the temperature is reduced to about 102° F cold sponges may then be employed The heart should be carefully watched and if evidence of pulmonary congestion appears venesection should be performed

Heat cramps may be prevented in large measure by supplying men exposed to high heat with salinized water (0 1 per cent sodium chloride solution cooled to about 50° F) Salt tablets are now commonly dispensed in industrial establishments presenting high heat hazards and though not as desirable are more convenient than salt solutions Cases of heat cramps may be treated with saline fluids rest and warm baths Sedatives may be helpful It is likely that the use of salinized fluids would be of value in preventing many of the effects of heat exhaustion among those exposed to continued high temperatures

ELECTRIC SHOCK

Electric shock may result when the body becomes part of the path of flow of current between poles of different potential Broadly speaking alternating currents are considered much more dangerous than direct currents With direct current the flow is in a single direction, with alternating current the direction is frequently reversed the frequency being expressed as cycles per second Fatal shock seldom results from contact with a direct current of less than 300 volts but the danger increases as higher voltages are attained Alternating currents if of few cycles (15 to 60) may cause death in well grounded subjects even at the 110 to 115 volts commonly used for home lighting but alternating currents of high voltage if of very high frequency may be handled with relative safety Maclachlan concluded from an analysis of 479 cases of electric shock that the severity of shock decreased or the success of resuscitative efforts increased as the potential of the circuit involved increased The resistance offered by the body as a conductor is a factor in determining the severity of shock The intensity of a current is measured by dividing its tension or voltage by the resistance in ohms the result being expressed in amperes The resistance of dry skin is about 50 000 ohms per square centimeter, varying in different parts of the body Moisture from sweating or wet clothing may lower the resistance to 1200 or 1500 ohms If skin resistance reaches 1200 ohms an alternating current of 110 volts may prove fatal The nature of the 'ground may determine the seriousness of shock A subject immersed in a water filled bath might be killed by a current which could be tolerated under other circumstances The duration of contact is also of great importance as the severity of shock increases with an increase in the duration of contact Prolonged contact with low voltages is more likely than with high voltages as in the latter case the victim very often falls clear aided by violent muscular contractions

Etiology —The tendency of currents of low voltage is to arrest the heart without affecting the respiration Alternating currents of low tension throw the heart in fibrillation High tension currents affect the central nervous system causing inhibition of respiration In one the result is heart death, and in the other respiratory paralysis It is inadvisable to generalize regarding the action of currents of moderate tension as many variable factors such as skin resistance grounding source voltage amperage duration of contact and kind of current determine the severity of the shock Much remains unknown concerning the mechanism and the effects of electric shock, although the studies of Urquhart Nahum and Hoff Maclachlan, Wills and their associates have contributed greatly to knowledge in this field

Morbid Anatomy —Postmortem evidences of electrocution are variable Extensive charring may mark the points of entrance and exit of the current or the burns may be slight or absent The superficial destructive effects of direct currents are usually more extensive than those of alternating currents The blood is often dark and is rarely coagulated Minute hemorrhages and areas of destruction may be found in the brain and cord Reference should be made to the detailed reports of studies of the effects of electric shock upon the nervous system published by Langworthy and Kouwenhoven and Morrison Weeks and Cobb

Symptoms —Loss of consciousness momentary or prolonged and burns of varying degree usually accompany severe electric shock Death may be instantaneous or result after some moments or hours Convulsions and priapism are common Those who recover from shock may suffer various after effects such as persistent muscular pain fatigue headache and nervous irritability Progressive loss of vision with opacity of the lens has been reported There are usually no permanent effects in those recovering from shock Because of the tendency to electrolysis of deep tissues and to the destruction of vessel walls the possibility of delayed hemorrhage must be kept in mind in the treatment of cases involving extensive burns

Prognosis —In cases of cardiac failure due to ventricular fibrillation death must be expected Respiratory paralysis often responds to artificial respiration (In experimental animals however cardiac function has been restored after induced ventricular fibrillation Hooker Wiggers) Jex Blake considered death due to (1) prolonged muscular tetany resulting in asphyxia, (2) ventricular fib-

rillation (3) respiratory failure through effects on the nervous system or (4) delayed effects of burns To these causes Langworthy and Kouwenhoven would add the more immediate effects of heat production and tissue coagulation

Treatment —When the victim is freed from the current artificial respiration is the measure first necessary in the treatment of electric shock It should be instituted at once as a delay of even moments may result in death Numerous official bodies concerned with electric shock have recommended the prone-pressure method which should be continued until rigor mortis sets in One case at least has been revived after eight hours of effort There is some evidence that the return of normal respiration is hastened by the supplementary use of oxygen or oxygen carbon dioxide inhalations Counter shock or stimulation by mechanical means has been advocated but there is little or no reason to believe that it is of value Different authors following the experimental work of Levy who showed that ventricular arrhythmias leading to ventricular fibrillation and death could be induced by conditions which stimulated the heart and by equivalent conditions which removed or reduced depressing influences have called attention to the often fatal consequences of administering adrenalin and other stimulating drugs in electric shock Nahum and Hoff discovered that acetyl choline given to experimental animals protects them from ventricular fibrillation and death when they receive an electric shock of the strength which normally causes fibrillation of the ventricles The important clinical application which is suggested by these findings is obvious Spinal punctures as a hospital procedure in the after treatment for persistent headache or signs of cerebral pressure are of some value

DISEASES DUE TO CHEMICAL AGENTS

CARBON MONOXIDE POISONING

CARBON monoxide is a gas produced by the imperfect oxidation of carboniferous material and is probably the most widely distributed of toxic agents It is colorless, in ordinary concentrations odorless, and is slightly lighter than air Ordinarily carbon monoxide does not appear in nature, but results almost entirely from the incomplete combustion of material containing carbon It may be encountered in the home through accidental leakage of manufactured gas from open burners and defective appliances and from incomplete combustion of various commercial gas products and in many industries particularly in coal mining in the steel industry *in processes utilizing gas heat and* in connection with the use of explosives in confined spaces It is found in smoke in compartments which have been painted with oil paints and sealed and in the exhaust of internal combustion engines Many deaths have occurred in closed garages from motor exhaust gas and manufactured gas long has been employed in suicide Coal gas contains about 16 per cent carbon monoxide blast furnace stack gas 28 per cent mine air after dust explosions 1 to 8 per cent and the exhaust from automobile motors about 7 per cent

Incidence —Without doubt countless persons are daily affected to some degree by carbon monoxide There is a striking variation in individual susceptibility but no evident racial or sex predisposition Children are believed to be more susceptible than adults probably because of their relatively greater respiratory exchange body weight considered Individuals with cardiorespiratory disease are handicapped when exposed to CO and the preexistence of certain nervous disorders may in persons poisoned result in aggravation of the nervous manifestations Some degree of acclimatization to carbon monoxide develops among those continually or frequently exposed to the gas and is shown in the lessening of symptoms during successive exposures to the same concentrations The possible explanation of this acclimatization is suggested by Killick as due to (1) a selective activity of the alveolar membrane producing either a secretion of oxygen from the alveoli into the blood, or an excretion of carbon monoxide from the blood into the alveoli, or (2) removal of carbon monoxide from the blood by oxidative or other processes in the tissues

Etiology —Carbon monoxide has an af*finity for hemoglobin two hundred to* three hundred times that of oxygen The reaction however, is reversible and depends upon the relative tensions of CO and O_2 in the alveolar air The gas is harmful in that it produces *anoxemia Death is due to respira*tory failure Though the problem has occasioned much study it has not been demonstrated that CO is of itself, specifically toxic Haldane has suggested that it may poison a catalyst of oxidation

Poisoning depends not only upon the CO content of inspired air but also upon the duration of exposure to the gas Particularly when exposed to moderate concentrations the blood does not attain *the full* saturation theoretically possible The maximum allowable concentration of carbon monoxide recommended by the American Standards Association is 100 parts per 1 000 000 parts of air by volume with atmospheric oxygen not below 19 per cent by volume for exposures not exceeding a total of eight hours daily and 400 parts per 1 000 000 parts of air by volume for exposures not exceeding a total of one hour daily

Morbid Anatomy —In the postmortem examination of victims of CO poisoning there is often noted a bright, cherry color of the blood Lining membranes are exceptionally red or show ecchymoses *Particu*larly important are pathologic changes in the brain characterized by hyperemia edema hemorrhage and diffuse degeneration Softening in the lenticular nucleus is regarded as the most typical *lesion in* CO

poisoning Chornyak and Sayers found in dogs that the cells of the cortex the corpus striatum the dorsal motor nucleus of the vagus and the dorsal sensory areas of the medulla were especially involved Neurons were severely damaged showing disruption marked chromatolysis and other degenerative effects Though still a matter of some dispute the effects of CO upon the nervous system are generally considered to be due essentially to asphyxia and not to immediate toxic action There have been reports of the disappearance of chromatin from adrenal capsules and of colloidal material *from the thyroid in cases of acute poisoning*

Symptoms.—Sayers and Yant observed that the character and severity of symptoms under any degree of blood saturation depended largely upon the duration of exposure and the accompanying muscular activity and further that with a blood concentration resulting from long exposure to a low atmospheric concentration there were noted more severe symptoms and after-effects than with a similar blood concentration resulting from a short exposure to a richer CO mixture In general a concentration of 0 06 per cent or 6 parts of carbon monoxide in 10 000 parts of air produces headache within an hour and unconsciousness in two hours while 0 1 per cent carbon monoxide or 10 parts in 10 000 produces unconsciousness in a little more than an hour and may prove fatal in four hours

Carbon monoxide may kill with great suddenness Victims of mine dust explosions have been found in attitudes indicating that there was no warning of impending danger Though headache is usually the first symptom the onset may be insidious There have been many cases displaying a progressive muscular weakness without loss of consciousness but with disturbances of memory the victim passing into a rather insouciant oblivion from which he may emerge quite promptly or from which he may pass into full coma

The after effects in those recovering from acute poisoning are extremely varied Headache vertigo muscular weakness and nausea are common More rarely encountered are serious disturbances of memory vision hearing and speech or psychoses neuritis and paralyses Cerebral hemorrhage has been observed some days after apparent recovery Pneumonia quite often ensues and a great proportion of hospital patients with CO poisoning have fever and a marked leukocytosis

Chronic poisoning by CO is believed by many authors to be a clinical entity It is certainly true that in many individuals repeatedly long exposed to small amounts of CO there are such evidences of disease as persistent headache malaise and an ill defined debility

Diagnosis.—Absolute diagnosis is dependent upon the identification of carbon monoxide hemoglobin The *pyrotannic acid* method affords a reasonably accurate quantitative estimation of CO in blood or air Of the laboratory methods the iodine pentoxide method though time-consuming is now the generally accepted standard of accuracy for CO analysis Carbon monoxide indicators are now available on the market which indicate by direct reading of a meter the percentage of carbon monoxide present They are sensitive down to 0 005 per cent and can be estimated to 0 001 per cent (1 part per 100 000)

Treatment.—Emergency treatment requires immediate artificial respiration if breathing has ceased preferably by the prone pressure method It may be employed advantageously for a short while even though the victim is breathing if asphyxia is marked The use when possible of an inhalator for the administration of oxygen or an O_2 CO_2 mixture is most desirable The inhalation of pure oxygen greatly accelerates the release of CO freeing it about four or five times as rapidly as does air A 7 per cent mixture of CO_2 in oxygen is advocated by Drinker and Henderson believes that a 10 per cent mixture is generally not excessive Oxygen alone will however serve admirably With the use of an O_2 CO_2 mixture the blood may be practically freed of CO in approximately half an hour

Patients should not be permitted to make any physical exertion and should be kept warm Seriously poisoned individuals after receiving emergency treatment may well be placed under observation in a hospital Medication and blood transfusions are rarely if ever indicated

BENZENE POISONING

Benzene (benzol C_6H_6, to be distinguished from petroleum benzine) is with disturbing frequency, the cause of serious and even fatal poisoning Benzene is obtained by the distillation of coal and the cracking of certain grades of petroleum Prior to the present World War less toxic substances were being substituted in many industrial processes but unfortunately owing to priorities of some of these notably toluol they are being replaced by benzene frequently without warning Benzene is used *widely in the manufacture of rubber goods* and artificial and patent leather, in lacquers paints printing processes as a solvent for fats and greases and motor fuels and for a great variety of other purposes The question *of benzene poisoning has been complicated* by the fact that commercial benzene contains a number of impurities such as thiophene and various homologues of benzene particularly xylene and toluene Extended investigation of the toxicity of such impurities has produced conflicting evidence but the preponderance of opinion favors the belief that they are not responsible for the effects generally attributed to benzene

Etiology—Benzene poisoning is usually caused by inhalation of its vapor though it can be produced by skin absorption Fifteen parts of benzene per 1 000 000 of air may, in some hours produce slight effects and twenty to thirty parts per 1 000 000 may induce coma in susceptible individuals These concentrations are below those frequently encountered in industry but it is now generally held that 100 parts per 1 000 000 should not be exceeded in any working space This latter concentration is accepted by the American Standards Association as the maximum allowable concentration for exposure not exceeding a total of eight hours daily Individual susceptibility to benzene varies greatly for reasons not determined

Morbid Anatomy—Most striking among postmortem findings are multiple hemorrhages throughout the body, uncoagulated blood, abnormalities of the bone marrow spleen and lymph nodes, and evidences of secondary infection

Symptoms—*Acute poisoning* may take place with great rapidity and death ensue in a few minutes Beginning with sudden dizziness the victim may quickly show great muscular weakness and lapse through drowsiness into coma Tremors delirium or convulsions are more infrequent There is often marked dyspnea with possibly, a sense of constriction of the chest, which may proceed to death from respiratory failure The pulse is small and rapid, the skin pallid or cyanotic occasionally showing ecchymoses

Chronic poisoning or subacute poisoning is of much more frequent occurrence manifested usually after days or months of exposure to benzene The early evidences of disease are commonly rather vague such as loss of appetite and weight headache, vertigo and muscular weakness As the condition progresses pallor is marked and is as*sociated with a true anemia* Dyspnea and air hunger may be striking Convulsions and delirium are rare Abdominal pain and gastro intestinal irritation with nausea and vomiting are common Quite typical are hemorrhages from the nose gums bowels kidneys and vagina as well as into the skin and mucous membranes The urine often shows evidences of nephritis with casts albumin, and blood Furunculosis may be encountered and possibly dermatitis related *to skin contact with benzene*

The blood picture may vary considerably from the so called classical changes Leukopenia neutropenia thrombocytopenia hypochromia eosinophilia and anemia may or may not be present Schwarz and Teleky report from their study of recent literature that the tendency now is away from a strict

classification of blood diseases on the basis of the particular blood element involved toward a realization that regenerative activity sets to work in all these cases with greater or less success and the resulting picture depends on the ratio of regenerative activity to the destructive effect of the injurious agent The bone marrow may not be affected or it may be aplastic hyperplastic or leukemic Resistance to infection is lowered

Diagnosis —The use of arbitrary criteria for diagnosis is not advocated The diagnosis cannot be made upon blood findings alone as these may simulate various blood dyscrasias The blood picture of agranulocytosis may be very similar to that produced by benzene and the other well known causes of leukopenia A history of exposure to benzol should be the determining factor in the diagnosis of benzene poisoning Yant and his colleagues report a marked decrease in the percentage of inorganic sulfates of the total sulfates in the urine of workers exposed to benzene They recommend the sulfate test not as a method for diagnosing benzene poisoning but as a reliable indication of benzene exposure

Prognosis —Many seriously poisoned patients have died after several days or weeks others recovering after prolonged illness The mortality among severe cases has in the past been about 50 per cent

Treatment —In acute cases with respiratory failure prompt artificial respiration is indicated The use of oxygen administered with an inhalator is advised Serious blood destruction and hemorrhage are best treated by blood transfusion possibly repeated many times The blood picture should be frequently observed Preparations of liver have been used to advantage Other treatment is symptomatic Because of lowered resistance to infection there may appear complications such as pneumonia bronchitis and cystitis

Prophylaxis involves careful control of industrial processes in which benzene is employed adequate ventilation the selection of healthy individuals as workers with benzene and the periodic examination of persons exposed to the end that those even slightly affected may be removed

ARSENIC POISONING

Arsenic poisoning is usually the result of exposure to one of the oxides of arsenic such as arsenious acid (As_2O_3) or to arsenical salts such as emerald green (aceto arsenite of copper) or lead arsenate Arseniuretted hydrogen (arsine AsH_3) is highly toxic but produces effects very different from those of arsenic salts Pure metallic arsenic is considered harmless

Incidence —Most industrial arsenic poisoning is seen in workmen engaged in extracting white arsenic (As_2O_3) from cobalt and arsenical pyrites in chemical works glass making cadmium plating in agricultural spraying and dusting in the use of sheep dip or in handling skins treated with arsenic Cases of poisoning have been reported from the use of the organic arsenic compounds from fruit sprayed with arsenic and from certain cosmetics and proprietary remedies

Arseniuretted hydrogen is produced when an acid and a metal either or both containing arsenic are brought into contact with a resulting liberation of nascent hydrogen which combines with arsenic to form the toxic gas Poisoning has occurred in chemical and galvanizing works in submarines

due to arsenic in storage battery plates or acid on ships carrying ferrosilicon which in contact with air and moisture tends to decompose and liberate AsH_3 and in the preparation of hydrogen for balloon inflation

Etiology —Arsenic oxide and the salts are local irritants to the skin and the mucous membranes of the mouth and respiratory passages, inhalation or ingestion of them produces local and systemic changes Acute poisoning is usually due to the use of arsenic with suicidal intent One grain (65 mg) of As_2O_3 has proved fatal Though the normal therapeutic dose of this substance is 2 mg the arsenic eaters of Styria can safely take over 400 mg twice a week

Arseniuretted hydrogen is primarily a hemolytic agent The inhalation of the gas over a period of several hours in a concentration of 30 parts per 1 000 000 will produce poisoning Rambousek claimed that 0 01 mg was highly toxic and the lethal dose as variously stated ranges from 100 mg to over 500 mg There is apparently marked individual susceptibility

Morbid Anatomy —Delepine reported that after poisoning by arsenic trichloride there is found granulo fatty degeneration of the heart liver kidneys pancreas and gastric and duodenal glands After death from poisoning by AsH_3 the liver has been found to be large and edematous with some evidence of fatty degeneration the kidneys large and the renal epithelium degenerated and necrotic Ecker found significant alterations in the nervous system marked by alterations in the ganglion cells and by regions of perivascular necrosis

Symptoms —Arsenic oxides or salts as dusts produce superficially a dermatitis or even ulceration about folds of skin as in the axillae or about the scrotum Increased pigmentation may be noted about the axillae the nipples the eyelids and on the neck Keratosis of the palms and soles may develop after prolonged ingestion of arsenic and skin cancer has been reported to follow the use of the drug The causal relation of arsenic to skin cancer is much disputed Scleroderma was found by Ayres to be associated with exposure to arsenic and to occur in patients who were eliminating arsenic in the urine The septum of the nose in some cases is perforated Legge states that the margins of the cartilage are not involved, and that perforation due to arsenic may thus be differentiated from syphilitic perforation Other symptoms are edema of the lids coryza pharyngitis and laryngitis With more serious poisoning vomiting abdominal pain, and diarrhea may be marked A peripheral neuritis with pronounced paresthesia is moderately common Paralysis similar to that produced by lead may result from the absorption of arsenic, the legs being more notably affected than the arms Tendon reflexes are diminished or lost Diffuse cerebral symptoms such as headache vertigo fatigue drowsiness and impairment of mental activity may result from chronic absorption

Poisoning by arseniuretted hydrogen is manifested usually three to six hours after the gas is inhaled by malaise vertigo weakness headache nausea and vomiting There may be abdominal pain and diarrhea A few hours later hemoglobinuria or hematuria and albuminuria are noted The pulse may become rapid and feeble and the respiration increased The reflexes are exaggerated and there are muscular pains in the extremities Within a day or two jaundice and a coppery cyanosis may be observed The liver and spleen are palpable Oliguria may develop and is of gloomy portent The red blood cells are much reduced possibly to near 1 000 000 the hemoglobin to 20 per cent or less In very severe cases there is a high color index and evidence of extreme blood destruction as well as of regeneration The leukocytes are ordinarily not involved though in some cases there is a slight leukocytosis There develops rarely after several weeks a transitory toxic polyneuritis with pain or anesthesia but no motor involvement

Diagnosis of arsenic poisoning is facilitated by careful inquiry into the nature of the patient s work and by chemical analysis of the urine hair and nails In connection with such analyses it should be noted that normal arsenic frequently has been found in the hair nails and excreta of persons not known to be exposed to arsenic (Schwarz and Deckert) Poisoning by AsH_3 is characterized particularly by the sudden onset, bloody urine and jaundice

Prognosis —Industrial poisoning by ar

senical oxides or salts is rarely fatal Manifestations of the disease may persist for weeks or months Poisoning by AsH_3, if severe is usually fatal within about a week death being due essentially to blood destruction The mortality is approximately 30 per cent Serious damage to the kidneys is almost inevitable and impaired renal function complicates recovery Convalescence is slow

Treatment of chronic arsenic poisoning is largely in the promotion of elimination through the kidneys and bowels In poisoning by AsH_3 oxygen should be promptly administered and the inhalations prolonged Transfusion may be necessary

MERCURY POISONING

Mercury has long been employed in the arts and in medicine Paracelsus (1493–1541) advocated its use for the treatment of syphilis and Mead (1673–1754) recommended the swallowing of the metal to a pound weight at least in cases of iliac passion in order that by its ponderosity it might restore the natural motion of the intestines

Acute Poisoning —*Etiology*.—Acute poisoning is usually caused by ingestion of bichloride of mercury accidentally or with suicidal intent The absorption of mercury administered therapeutically by mouth injection inunction or in vaginal douches may produce a mild acute or subacute poisoning as does quite rarely, an industrial exposure to massive doses of mercury vapor Ingestion of 0 1 Gm of mercuric chloride may result in acute poisoning although usually 1 Gm or more is required to render the condition serious Mercury is quickly absorbed from the stomach and after brief storage in the liver, is widely distributed

Morbid Anatomy.—In cases dying within twenty four hours of ingestion of mercury there are observed marked gastritis and possibly some nephritis Cases dying within the period from two to seven days after ingestion show a necrotic nephrosis and marked colitis Those dying after one week show a tendency toward healing of the gastric and renal lesions but a severe gangrenous colitis

Symptoms.—The onset is usually rapid within a few minutes after ingestion abdominal pain develops especially in the epigastrium This is fortunately in most cases associated with vomiting and rejection of a portion of the ingested poison There is a metallic taste and often a marked stomatitis and congestion or even ulceration of the pharynx and esophagus The vomitus may early contain blood streaked mucus Stools are loose and bloody There may be prompt collapse and in exceptional cases delirium and convulsions Examination of the blood during the first few days shows blood nitrogen increased the whole blood chlorides reduced and the alkali reserve lowered The urine is strongly acid to methyl red and the renal function is low When the intoxication is not promptly fatal signs of gastro intestinal inflammation and striking evidence of injury to the kidneys usually continue Albumin casts and blood appear in the urine a few hours after ingestion of the poison and gradual suppression of the urine and possibly anuria may be noted The condition may appear very similar to the uremia of chronic nephritis with headache coma and edema

Diagnosis.—It is important to ascertain with certainty that mercury has been ingested In hospital practice many cases treated as mercury poisoning are wholly unproved Some of the newer methods for the determination of mercury are the electrolytic dithizone selenium sulfide spectrographic and photo electric Spectro-analysis

has become a valuable diagnostic aid Small amounts of mercury have been found in the urine and stools of apparently normal healthy individuals

Prognosis —If mercurial salts are vomited within fifteen minutes of ingestion the patient usually recovers The frequent estimation of blood nonprotein nitrogen is of aid in prognosis The majority of deaths occur within the first two or three days The mortality among proved cases may run over 40 per cent though with prompt and thorough treatment in hospital it should be less than 10 per cent If death is not caused by shock or severe gastro enteritis it is usually attributable to kidney damage

Treatment —Emergency treatment may include induced emesis and gastric lavage or treatment of shock The treatment described by Weiss is devised to overcome the effects produced by the poison rather than to provide an antidote to mercury It may be outlined as follows

The stomach is immediately washed with a saturated solution of sodium bicarbonate the operation being continued until the washings are clear At least 2 liters of the solution should be used Before withdrawing the stomach tube 6 ounces of a saturated solution of magnesium sulfate are administered A soapsuds enema is then given As soon as possible thereafter an alkali should be injected intravenously (Fischer's solution crystalline sodium carbonate 10 Gm sodium chloride 15 Gm distilled water 1 liter or a 4 per cent solution of sodium bicarbonate) in quantities as large as 1000 to 1800 cc if there is no disturbing cardiovascular disease Second or third injections should be given on successive days if more than 0 5 Gm (7½ grains) of mercuric chloride was ingested or if there is striking evidence of renal injury

From the onset a beverage made by dissolving 4 Gm (1 teaspoonful) of potassium bitartrate and 2 Gm (½ teaspoonful) of sodium citrate in a glass of water orangeade or lemonade is to be administered six to eight times daily Weiss has seldom used rectal irrigation or hot packs He permits a liberal diet after diarrhea ceases The treatment is controlled by urinalysis and an effort is made to keep the urine alkaline to methyl red

The use of sodium formaldehyde sulfoxalate and of calcium sulfide intravenously has been proposed and there are numerous advocates of sodium thiosulfate Despite the enthusiasm of those who have employed the latter by mouth and intravenously well controlled laboratory studies have failed to demonstrate its utility (Young and Taylor) Berger and his associates believe that except in cases with shock immediate cecostomy with constant lavage is warranted

Subacute poisoning is ordinarily caused by the excessive therapeutic use of mercury The common symptoms—salivation gingivitis and diarrhea—subside upon the withdrawal of the drug

Industrial Poisoning —Industrial mercury poisoning is almost invariably a chronic intoxication resulting from the inhalation of volatilized mercury for a long period One milligram of mercury per 10 cubic meters of air has been proposed as probably the upper limit of safe exposure The most hazardous trades are the production of mercury and its derivatives the manufacture of scientific apparatus (thermometers and barometers), the preparation of hatters fur and felt hat making the extraction of gold and silver by amalgamation, the application of anti fouling plastic paint for the protection of hulls of warships against the growth of aquatic life and the preparation and handling of the fulminate of mercury as a detonator of explosives Since the recent discovery of a substitute for mercury in the treatment of fur certain states by agreement with the manufacturers of felt hats have issued regulations prohibiting the use of mercurial carrot in the preparation of hatters fur or the use of mercurial carroted hatters' fur in the manufacture of hats

Symptoms —Chronic mercurialism has various manifestations far from all of which may be observed in any one case The most typical symptoms are included in the first three of the following groups

1 STOMATITIS SALIVATION a metallic taste reddish brown discoloration of the buccal mucosa gingivitis loosening of the teeth and occasionally a marking of the gums similar to the lead line

2 ERETHISMUS MERCURIALIS a peculiar psychic disturbance characterized by ready excitability and a strange shyness in the presence of strangers a symptom of great interest and importance, insomnia headache vertigo mental depression and dulness and rarely hallucinations

3 TREMORS of the orbit lips tongue fingers and limbs These are usually moderately fine at first but at intervals become a coarse jerking They may become very severe and in rare instances involve contractions of the limbs of such violence as to require restraint The tremor is inten

tional and subsides during rest Under observation it may increase and diminish rhythmically recurring When it is marked the patient may require assistance in eating and in other activities Weakness of both the flexor and extensor muscles of the hand and forearm has been reported but marked paresis is rarely if indeed ever caused by mercury Polyneuritis is said to result occasionally from exposure to mercury There is no ataxia and the reflexes are not notably affected

4 Albuminuria and High Blood Pressure —While the severe nephritis associated with acute mercurial poisoning is not associated with the chronic type these symptoms appear with such frequency as to warrant the belief that the kidneys are usually involved in chronic poisoning

5 Loss of appetite indigestion and diarrhea are occasionally observed There is loss of weight in severe cases The blood is normal except for a moderate secondary anemia

Dermatitis characterized by erythema and desquamation is not uncommonly produced by contact with mercuric chloride or even by ingestion of mercury In susceptible individuals fulminate of mercury produces severe dermatitis Punched-out and penetrating ulcers may develop about the fingernails and knuckles The conjunctivae and the mucous membranes of the mouth nose and larynx are often affected

Prognosis—There is apparently no acquired immunity to mercury The severity of symptoms is usually determined by the length and degree of exposure to the poison While most severe symptoms tend to decrease when the subject is removed from contact with mercury such manifestations as erethism and tremor may persist for a long time Tremor particularly has been observed many years after the last exposure Chronic mercury poisoning is only indirectly a cause of death

Treatment should eliminate the metal through the bowels kidneys and skin The symptoms are relieved by suitable hygiene A diet high in vitamin B complex has been suggested

Mercury dermatitis may be prevented and to some degree relieved by application of a 10 per cent solution of sodium hyposulfite A 2 per cent solution may be used as a wash for conjunctivitis

CHRONIC BROMIDE POISONING

(*Bromism*)

Bromide therapy first introduced in 1857 has been widely used on account of its sedative action in the treatment of nervous disorders in idiopathic epilepsy and kindred states Self medication with proprietary bromide preparations which are extensively advertised to the public and readily available without prescription is common and it is important therefore that the physician ascertain the extent of previous or simultaneous consumption of these preparations by the patient when prescribing bromides

The bromides are readily absorbed from the stomach when given by mouth and exert a depressing effect on the central nervous system especially on the brain and medulla Their prolonged and indiscriminate use however may cause an intoxication often accompanied with a transitory delirium due to accumulation of bromides in the blood and other body fluids This accumulation is at the expense of the body chlorides which fall in the same proportion and are excreted by the kidney in preference to bromides

Symptoms —The clinical features particularly in the milder forms of bromide intoxi

cation may be somewhat masked by the *underlying disturbance or disease for which* the bromide was administered and the only clue may be an apparent exaggeration of the preexisting illness The patient may complain of headache and dryness of the mouth and show evidence of weakness and in some instances a slight rise in body temperature In the more severe bromide intoxications the symptoms and signs of toxic delirium predominate and are manifested by fear, delusions hallucinations disorientation visual disturbances and disturbances of memory and of equilibrium

Diagnosis —While the symptoms of a toxic delirium may be sufficiently suggestive to permit clinical recognition in a number of cases, a laboratory determination of bromide in the blood should always be made Although a variety of methods for determining bromide concentration has been suggested Wuth s modification of the Walter *Hauptmann method is popularly used* This consists of adding gold chloride to a protein free filtrate of serum and noting a color change in the mixture from yellow to a reddish brown due to the formation of gold bromide For estimation of the amount present the mixture is compared with a standard in a colorimeter or by means of a comparometer

A blood bromine level averaging 200 mg of sodium bromide for each 100 cc of serum is very apt to produce intoxication although susceptible persons may show symptoms with a much lower level and conversely others more resistant may tolerate higher levels with impunity

While admitting the adequacy of the gold chloride method for the initial diagnosis of bromide intoxications Gray and Moore point out certain inaccuracies in the method and suggest that the determination of urine and blood chlorides along with bromides is a far better indication of the progress of treatment or of the validity of a diagnosis

An *acneiform type* of eruption if present is an aid in the diagnosis of bromide intoxication but may be absent in a large proportion of cases

Treatment.—Treatment consists of discontinuing the bromides plus the administration of sodium chloride in doses of 2 to 4 Gm three times daily in addition to that contained in the diet Salt can be pleasantly administered by bouillon cubes, each of which contains 2.5 Gm of sodium chloride Fluids should be moderately forced and the patient should be given a high caloric diet rich in vitamins Bondurant and Campbell have ad*ministered adrenal cortex* extract in combination with sodium chloride to a small group of cases of bromide intoxication and found the combined therapy of value in promoting excretion of bromide and in alleviating bromide effects

LEAD POISONING

Ever since lead has been used in industry and the arts, lead poisoning has been a well known occupational disease Physicians of the Middle Ages associated colic and *palsy with the poison* but to Tanquerel des Planches (1831) belongs the credit of first correlating all the manifestations of the intoxication It is now known that *the blood* striated and smooth muscle, and the nervous system are most strikingly affected and that the disease is usually associated with inhalation of the dust of lead or of its compounds and with the ingestion of contaminated foods and liquids

Incidence—Although lead poisoning is *still one of the most important* industrial diseases the relative frequency of occurrence is far lower than it was fifteen years ago *Pioneering work of Oliver and Legge* in England and of Alice Hamilton in America

proved that prevention is possible, and as a result of the legislation and factory improvement incited by their investigations the number of cases in industry is rapidly declining About 150 industries involve some exposure to lead The dusty trades are the most hazardous and include the manufacture of white and red lead of storage batteries and of pottery as well as spray painting and fumes from acetylene torch welding

Etiology —Outside of industry lead poisoning is infrequent During prohibition the making of wines and liquors in vessels which contained lead alloys caused some plumbism in the United States Many years ago this was such a common cause of poisoning in the cider district of Devonshire that Devonshire colic became a well known disease In the sixteenth century Colica Pictonum was epidemic in France near Poitiers and later this was found to be caused by the lead added to wine to prevent souring On standing wine thus treated could not turn to vinegar because the lead reacted to form lead acetate

Other less frequent causes of plumbism are the drinking of rather acid water in which lead pipe has been immersed the use of lead salts in hair dyes or cosmetics the chewing of painted surfaces by children and the ingestion of lead salts with suicidal intent or to cause abortion The amount of lead which enters the organism need not be large to produce severe symptoms as is shown in a case of poisoning reported after the ingestion of 1.33 Gm of lead acetate (less than 750 mg of metallic lead)

It is now known that lead may be absorbed from the gastro intestinal tract from the respiratory tract and even from the mucous membranes of the nose and mouth The respiratory tract is the more dangerous path of entry because inhaled lead dusts may enter rapidly into the circulation and so become widely distributed while most of the lead absorbed from the gastro intestinal tract is caught by the liver and excreted back into the duodenum Subcutaneous or intramuscular deposits of lead enter the blood stream so very slowly that intoxication from bullets if it occurs at all is very rare Absorption of inorganic lead salts from the skin is probably negligible though there is a source of danger from some organic compounds, such as lead tetra ethyl which are soluble in lipoids

Lead is a cumulative poison because it is stored in relatively large amounts in the solid portion of the bones Until it is liberated from the skeleton this deposit does no harm During absorption the blood stream carries lead to all the organs, especially to the bones liver kidneys and intestines After active absorption has ceased, almost all the lead in the body (more than 95 per cent) is to be found in the bones from which it is excreted extremely slowly Symptoms of lead poisoning may appear when lead is circulating in sufficient concentration throughout the organism as a result either of absorption from outside sources or of liberation from the deposit in the bones

Lead is excreted through the gastro intestinal tract and the kidneys The larger part of lead eliminated is in the feces but the fact must be kept in mind that during active absorption of lead the feces also contain some which has been ingested but has never been absorbed The amounts of lead excreted in urine are usually very small

Morbid Anatomy —Some claim that an abnormally high incidence of arteriosclerosis chronic interstitial nephritis gastric ulcer and cirrhosis of the liver are found in lead workers None of these is established except nephritis which is rare and a late manifestation In permanent palsy many of the anterior horn cells in the cord disappear The affected muscles are atrophic and fatty and the muscle tissue itself is gradually replaced by fibrous material There are no other definite pathologic changes except after lead encephalopathy in children when cerebral atrophy may result

Symptoms —*Acute Poisoning* —True acute poisoning is to be seen only after the sudden ingestion of large doses of lead and is very rare The symptoms are vomiting and collapse and there may be a peripheral destruction of large quantities of red blood cells accompanied by acute anemia and sometimes by hemoglobinuria The marked general weakness loss of appetite diarrhea dehydration and epileptiform convulsions may result in death or in a more chronic type of poisoning This should not be called acute lead poisoning because the symptoms are those of the more chronic type

Intoxication —In chronic plumbism the patient usually suffers from weakness lassitude obstinate constipation and often from intense colic A peculiar pale pasty appearance of the skin is quite characteristic of the condition The several features peculiar to lead intoxication will here be considered individually

(*a*) CHANGES IN THE BLOOD —One of the earliest evidences of lead poisoning is a change in the nature and number of red cells in the circulating blood A marked destruction of erythrocytes in the peripheral circulation is accompanied by increased production of red cells The counterbalancing of

Fig 47—Palsy of the Aran Duchenne type due to lead poisoning

the loss of red cells by stimulation of bone marrow activity maintains the cell count above 3 500 000 or 4 000 000 cells per cubic millimeter so that anemia is usually not so severe as the pallor of the patient would suggest Recent investigations of the mechanism of destruction of blood have shown that lead reacts with inorganic phosphate to form insoluble lead phosphate and acid on the surface of the cells This renders the cells inelastic and brittle so that they are broken more easily than normal cells by the traumata suffered in circulation

The most characteristic change in the blood is the appearance of "stippling" a *punctate basophilic* granulation in the cells which is best demonstrated by dilute Unna's alkaline methylene blue stain This may continue for some months after absorption of lead has ceased Stippled cells are probably degenerating young reticulated cells Their presence in the blood is not absolutely pathognomonic of lead poisoning as a few may be found in cases of pernicious anemia leukemia severe infections, particularly in children, and in normal blood, but there are *more than 1000 stippled cells* per million *red cells* in the chronic type of lead and radium intoxication An increasing stippled count usually precedes the onset of a toxic episode as it indicates a damage to body cells Stippling is therefore one of the reliable criteria for establishing the diagnosis of lead intoxication

(*b*) THE LEAD LINE —The "lead line" on the gums is a second important sign of plumbism and is very valuable in making a diagnosis It is due to a deposit of lead sulfide about the blood vessels in the tips of the papillae and therefore appears most plainly about pyorrheic gums When examined with a lens it has a punctate appearance A piece of paper inserted between the gum and tooth distinguishes stippling from staining of the tooth root The peculiar localization differentiates this from the other pigmentations of the mouth which are more diffuse The lead line is practically pathognomonic of lead absorption but not of poisoning It may persist for many months after exposure to lead has ceased It must be distinguished only from the similar line produced by bismuth

(*c*) COLIC —Abdominal colic is the usual manifestation of lead intoxication It is usually preceded by constipation and indefinite abdominal pain While the character of this colic in individual cases varies greatly it is usually very intense and prolonged The pain which is generally felt below the umbilicus is often relieved by pressure During attacks the abdomen is scaphoid in shape not tender to pressure and while resistant shows no evidences of true abdominal muscle spasm Paroxysms of pain occur when peristaltic waves approach areas of marked tonic spasm in the intestines This lead colic is often very difficult to differentiate from an acute abdominal inflammation but diagnosis

is aided usually by *other signs of lead poisoning* It should be remembered that in lead poisoning the white count is only slightly increased if at all that there is a relative lymphocytosis and no fever While intestinal colic is the usual manifestation similar attacks have been described in any viscus composed of smooth muscle

(*d*) Palsy —Palsy has been recognized as one of the symptoms of lead poisoning for many years Although in 1834 Tanquerel des Planches reported that it occurred in 10 per cent of the 1200 cases he had examined it is now relatively rare because of improvements in industrial management A general weakness and tremor of fatigued *muscles usually precede the actual onset of* paralysis These may well be demonstrated by extending and actively spreading the fingers They have been shown by Steiman to be associated with difficulty in resynthesizing creatine triphosphate The paralysis which may follow if lead exposure continues is similar to peripheral neuritis and is usually rapid in onset and painless One of its very striking characteristics is its marked localization in the most used and fatigued muscles the extensors of the wrists and fingers of the dominant hand are first attacked in a startlingly specific manner producing the characteristic finger and wristdrop and leaving flexor and pronator muscles uninvolved Paralysis may also appear in the peroneal muscles of the legs and produce a steppage gait Optic neuritis has also been described After absorption of lead stops muscle weakness requires weeks but true palsy requires months for a return of function If exposure to the poison continues paralysis may be permanent and progressive

(*e*) Psychosis —In many cases of lead poisoning there is mild mental depression while occasionally transient delirium and convulsions occur Rare cases show severe cerebral involvement characterized by marked delusions *and mania leading to convulsions* and death This psychosis may closely simulate general paresis in its clinical manifestations although the Wassermann *reaction* is not positive The spinal fluid shows only an elevated pressure

Lead poisoning is usually made manifest in children by epileptiform convulsions This is particularly serious as it may result in *death or in subsequent mental retardation* with cerebral atrophy

(*f*) Gout —In England gout is frequently reported in chronic cases It is certainly extremely rare in America

(*g*) Degenerative Changes —That the late manifestations of lead poisoning are largely degenerative and are caused by the continued action of the lead stream is said to be shown by the occasional appearance of arteriosclerosis contracted kidneys and a resulting high blood pressure and hypertrophy of the heart All of these manifestations however seem no more common in lead workers than in the average individual

Diagnosis —The diagnosis of lead poisoning *is often difficult because evidence of ab*sorption without signs of actual intoxication may frequently be observed Usually unless at least two symptoms characteristic of the poisoning appear a definite diagnosis of plumbism should not be made The best evidence of intoxication is marked stippling of the red cells but lead line colic constipation anemia muscle weakness and wrist drop are also important In children the epiphyseal ends of the bones disclose a dense line by x ray After union of the bone epiphyses no lead line in bone can be found by x ray The excretion of lead in the urine and feces is also significant though it is found in the urine in many individuals not known to be exposed to lead The greater part of the lead excreted is to be found in the feces but its presence is of little diagnostic value unless all possibility of swallowing lead has been removed Lead in the urine however gives an index of the amount of exposure to lead Up to 0 08 mg per liter is considered a normal amount This level rises higher as lead exposure increases and symptoms are apt to appear when urinary lead is above 0 2 mg per liter This proves that lead has been absorbed by the organism but is not in itself a proof of intoxica*tion*

Final diagnosis depends upon all of these considerations but usually requires at least two of the described features In some cases both the lead line and slight stippling appear in workers without other evidences of poisoning but marked anemia colic or nervous lesions are usually deciding factors in diagnosis

Lead poisoning often appears after prolonged exposure but occasionally even after exposure has ceased This tardy development of symptoms is probably caused by liberation of the lead deposit in the bones which occurs during severe illness or alcoholic debauches It has also been once reported after taking potassium iodide Thus if lead is held harmlessly within the body some change in the general metabolism may precipitate an attack of poisoning The disease should always be thought of in acute abdominal crises as it not infrequently is the cause of unnecessary surgery

Prognosis —The prognosis depends upon the type of symptoms Colic usually disappears within a few days with suitable treatment while anemia constipation and general debility remain for weeks Palsy disappears very slowly and in some cases is permanent Severe psychoses are often fatal but those patients who survive rarely show chronic psychoses usually these disappear promptly and completely The mild depression which is so common a symptom is lost as other acute symptoms subside The encephalopathies of children may lead to mental deterioration

Prophylaxis —Dust and fumes are the most common sources of poisoning at the present time If proper precautions are taken by workmen and employers to avoid all dust hazards by suitable ventilation aided by the use of respirators intoxication may be very largely prevented The incidence of poisoning among painters may be greatly reduced by the use of sandpaper which can be moistened Clean hands and clean places to eat must be insisted upon The toxicity of lead varies so much with individuals that no definite prediction may be made as to the amount which will cause symptoms of poisoning to appear although Legge states that a continued absorption of more than 2 mg per day may produce intoxication

Treatment —Relief of the severe colic of lead poisoning often demands much medical ingenuity Intravenous calcium gluconate or calcium chloride usually gives prompt relief for several hours Atropine in large doses or nitroglycerin may also be tried A hot water bottle may be comforting If diagnosis is certain a saline *cathartic* or an *enema* is also desirable *Morphine* is rarely necessary to relieve the pain

After the subsidence of acute symptoms the purpose of the treatment is to gradually eliminate lead from the body Since it was first recommended by Melsens in 1840 *potassium iodide* has been employed to increase the excretion of lead The initial doses should not exceed 1 Gm per day, and the amount should then gradually be increased

A more effective *method of treatment* has been developed which is dependent upon the parallel metabolism of lead and calcium (Aub and Minot) Thus it is probable that storage of lead may be reduced by keeping the bones filled with calcium by means of an adequate intake of milk When patients are suffering from lead colic a prompt relief may be obtained by the slow intravenous injection of 10 cc of a 20 per cent sterile solution of calcium gluconate After the pain has been relieved by this method a strenuous cathartic is given In acute cases a diet containing much calcium should be given This consists of 1 to 2 quarts of milk and 6 to 8 Gm of calcium lactate daily it tends to reduce the circulating lead After disappearance of acute symptoms such a diet should be replaced by one containing as little calcium as possible (No milk eggs nor green vegetables) With this large doses of ammonium chloride should be given to accentuate the negative calcium balance and thus tend to liberate lead from the bones This should be continued for four to six weeks Recent therapeutic suggestions have included the use of vitamin C and also the use of citrate to lower ionization and to maintain solubility of lead in the blood stream

Saline cathartics have long been recommended to relieve constipation They probably do not increase the excretion of lead Treatment for the *anemia* of lead poisoning should be like that for any secondary anemia *Palsy* best responds to galvanic current and massage and should be treated like a peripheral neuritis Disappearance of the acute symptoms of plumbism does not signify that the disease is cured Treatment to stimulate elimination of lead and to regulate the bowels should be continued for some weeks after the more distressing symptoms have been alleviated

It is always desirable for a patient suffering from any of the symptoms of lead poisoning to avoid further exposure to lead

RADIUM POISONING

Definition —The term radium poisoning should be restricted to the harmful effects caused by the swallowing inhalation or injection of radium mesothorium or other long lived radioactive substances Radium poisoning is similar to lead poisoning in that in both conditions there are actual deposits of the heavy metals (radium or lead) in the body tissues

There are also deleterious effects produced by radium (and x rays) which do not constitute radium poisoning but because such injuries may produce leukopenia anemia and even death they are closely allied to radium poisoning These conditions result from undue exposure to external penetrating noncumulative radiation given off by these physical agents and include the occasional harmful effects of radium or x rays applied externally in the treatment of cancer or other conditions and from the industrial use of both radium and x rays in the examination of castings and steel armor

History.—Radium poisoning was unknown until 1925 when Martland and his coworkers reported deaths among dial painters formerly employed in a New Jersey plant. These workers while painting luminous watch dials pointed their brushes in their mouths and swallowed small amounts of radium paint The symptoms diagnosis during life and after death autopsy findings microscopic pathology toxicology and treatment were described for the first time and the existence of radium poisoning definitely established

Etiology —The *ingestion of radioactive luminous compounds* by workers painting luminous dials on watches and clocks has been the main source of radium poisoning This danger practically ceased in 1925 when workers stopped licking their brushes and there was a lessened demand for watches with luminous dials The great increase in aviation however during the past few years and the requirements of the Second World War have created an enormous demand for luminous dials especially for navigation purposes For example a large bomber may have 100 dials in the cockpit with the equivalent of more than 400 micrograms of radium Thus the dial painting industry again employs hundreds of new operators Furthermore no satisfactory mechanical method of applying the radium paint has been found Nor is the elimination of radium paint feasible since the glare of an artificial source of light would make accommodation difficult for night flying and furthermore this might be shot away

Dial painting has therefore again become an important hazard and every protective device must be used to prevent radium poisoning In spite of all precautions recent examinations of a large number of dial painters most of whom have worked at this occupation for less than two years revealed that more than 7 per cent of the girls have already accumulated dangerous deposits of radium in their bodies

Other occupational exposures to radioactive substances occasionally occur In the *mining of radium* there is less risk than in the *refining* of the product The chief dangers are the *inhalation of radon* and radioactive dust from the ores and early products of extraction

Chemists physicists laboratory hospital and other workers exposed to radioactive substances may also develop radium poisoning, through inhalation or ingestion of emanation or dust However, the main hazards are refining of radium and mesothorium, the tubing of partly aged radium material the preparation of luminous paint needles plaques and containers, the explosion of bombs or radium apparatus containing highly concentrated emanation, the dusting of dishes etc The possibility of direct bomb hits on large emanation plants during air raids must be considered but most of these dangers can be avoided by proper protective measures

Drinking of *artificial waters containing radioactive salts* (radium waters) has caused a number of deaths The use of such waters is extremely dangerous and must be prohibited

Drinking of *artificial waters containing only the gas emanation* (radon waters) is thought to be harmless since most of the gas escapes quickly At least there is no proof that they have produced radium poisoning This group includes waters charged by various crocks emanators and activators

Further drinking of *natural spring waters which contain only emanation* is not considered dangerous Beneficial results of treatment at radioactive spas are due largely to the psychic effect and the regular hygienic habits of the patients There is no scientific basis for the therapeutic use of any of these waters or baths because of their radioactive properties

Patients may be poisoned by radium and radioactive substances unwisely employed for therapeutic and diagnostic purposes Intravenous injections of the soluble bromides and chlorides of radium have been used for almost every ailment especially gout rheumatism senility cancer and leukemia As there is a lack of direct evidence of their curative value in any medical condition the therapeutic injection of radium or radioactive salts is unwarranted and is distinctly dangerous because of the cumulative effects

The diagnostic use of *thorium dioxide solution by intravenous injection* for roentgen visualization of the liver spleen and arteries and its injection into the brain or various sinuses have all been described despite repeated warnings of its radioactivity and toxicity Observation of patients for one or two years is insufficient since harmful effects may occur after a much longer period Animal experimentation has shown that thorium dioxide causes hepatic necrosis and cirrhosis and sarcomas have been produced in mice and rats by subcutaneous and intraperitoneal injections

Recent advances in physics especially with the development of the cyclotron have led to the induction of radioactivity in nearly all the elements Such radioactive elements when injected behave as tagged atoms but chemically resemble their inactive relatives Acting as tracers these may furnish important data in cell metabolism Their selective deposition in the tissues (phosphorus in bone iodine in the thyroid) introduces a new method of selective irradiation which may prove useful in the treatment of cancer leukemia and allied conditions The injection and use of such *artificial radioactive substances* would theoretically at least be harmless since most of the radiation from these substances is *short lived* (minutes hours or a few days)

Toxicology—When radioactive substances are ingested over a long period very small amounts enter the circulation That portion not excreted is constantly subjected to phagocytosis by the cells of the reticulo endothelial system in the liver spleen and bones

In time the liver and spleen rid themselves of these deposits and eventually over 98 per cent of the radium not eliminated is stored in the bones as carbonates, phosphates and even sulfates

The toxic effect of radium when deposited in the bone is due entirely to its radiations consisting in large part *(92 per cent)* of alpha rays the effect of the small amount of beta and gamma radiation is practically negligible This incessant alpha bombardment irritates the bone marrow and its blood forming centers

A similar storage eventually occurs after *the inhalation or intravenous injection* of radioactive substances with the exception that when the respiratory tract is the portal of entry the lungs may show considerable radioactivity

Morbid Anatomy —The tremendously disruptive effect of the alpha particle causes atomic and molecular disintegration within the tissues In time irritative stimulation sets up a hyperplastic red marrow characterized by a packing of the spaces with primitive stem cells Megaloblastic erythropoiesis is a prominent feature and the peripheral blood often resembles addisonian anemia With the exception of eosinophilic myelocytes which are numerous granulopoiesis is greatly impaired Hence leukopenia with an agranulocytic syndrome is seen in some cases This hyperplastic irritative embryonal marrow is the *first stage of radiation osteitis*

After a period of months or years the process subsides in patchy areas over the skeleton and an intensely inflammatory and very cellular replacement fibrosis develops This is the *second stage of radiation osteitis* Many of the fibroblasts show mitotic figures and hyperchromatism and these areas can be distinguished from sarcoma only with great difficulty *It is in these areas that sarcoma undoubtedly arises*

In radium poisoning the radioactive deposits act as *carcinogenic agents* and must be added to that rapidly growing list of agents now known to produce cancer All such agents induce cancer only after a lapse of time which occupies a *considerable fraction of the normal span of life* of the individual or experimental animal In human beings suffering from radium poisoning it usually takes ten or more years for bone sarcomas to develop and in experimental rats more than one year is required

The *bone tumor* characteristic of radium poisoning is an *osteogenic sarcoma* of the medullary and periosteal variety although periosteal fibro arcomas have been observed Because of their anaplastic qualities and rapid growth however many are predominantly osteolytic and in these bone formation may often be scant

Most of the bone sarcomas have occurred in dial painters who swallowed radium paint They have also been caused by the drinking of radium water containing salts in solution and after intravenous injections

If however the portal of entry has been the respiratory tract such as occurs from undue inhalation of emanation and radioactive dust *primary carcinomas of the bronchi* may develop Examples of these are seen in the miners of Joachim tal and Schneeberg and in physicists who have died from lung cancer Bone tumors in these cases have not been observed since the chief deposits have been in the lungs

The *third* or *final stage of radiation osteitis* is one of healing with almost entire subsidence of all inflammatory reactions The marrow is entirely replaced by an old noncellular fibroblastic tissue The bones become soft partially decalcified and crippling bone lesions occur

Symptoms —Radium poisoning is a slow insidious chronic disea e and after exposure the patient may remain in good health for many years before clinical symptoms occur

In rare instances massive doses of radioactive substances especially thorium X have been followed by *acute radium poisoning* and severe fatal anemia

Patients having relatively large amounts of radioactive substances deposited in their bodies (the equivalent of 20 to 180 micrograms of radium) usually develop extensive radiation osteitis throughout most of their bones within one to five years A superadded bacterial infection from the teeth often leads to extensive necrosis of the mandible and maxilla Anemias of the regenerative pseudo aplastic or pernicious type may develop The usual type of anemia is clinically difficult to differentiate from the refractory anemias of the aplastic type (the marrow however is hyperplastic) Hemorrhages from the mucous membranes and intestinal tract are unusual Most of these cases die as the result of extensive jaw necroses the severe anemias and from terminal sepsis

Patients having smaller amounts of radioactive substances in their bodies (the equivalent of 2 to 20 micrograms of radium) usually escape the extensive jaw necroses and anemia but develop crippling bone lesions usually within eight years Coxa vara deformities of the spine moth eaten lesions of the flat bones of the skull and spontaneous fractures are most frequently encountered

Some old cases lose most of their radioactivity but still suffer from crippling lesions due to extensive decalcification However definite bone destruction and bone sarcoma

have been noted with as little as 0.5 of a microgram of radium in the entire body

The symptoms directly attributable to the sarcomas are identical with those produced by ordinary sarcoma of the bones Diagnosis depends upon the presence of a bone tumor as shown by x rays and proof that the victim is radioactive The prognosis and treatment are the same as those of any malignant bone tumor Since many radium sarcomas remain localized for a long time amputation should be seriously considered

Diagnosis —Whenever there is a history of industrial or occupational exposure to radium or other radioactive substances or of their therapeutic use or their injection for diagnostic radiographic purposes the possibility of radium poisoning exists

Radium poisoning can only be *proved* by the demonstration of radioactive deposits in the body in amounts greater than what is now considered the *tolerance dose* (the equivalent of 0 1 microgram of radium in the entire body)

In order to recognize radium poisoning in its inception long before clinical symptoms appear and at a time when further exposure may be stopped and elimination therapy used to best advantage very sensitive methods of testing are required since amounts far below the tolerance dose of 0 1 of a microgram must be detected

The original electroscopic methods were seldom able to detect with any degree of accuracy deposits of radium less than 5 micrograms Such methods are now obsolete

Gamma ray detectors employing highly improved Geiger Mueller tubes are much more sensitive but body deposits below 0.5 of a microgram are difficult to record and surface contamination of the body cannot always be eliminated as a source of radioactivity

At the present time the only method that will meet the requirements is the *Expiratory Breath Analysis of Evans* This method requires specially constructed nonportable apparatus and can only be performed by competent physicists trained in modern methods of radon and thoron analyses The expiratory air may be collected in special containers and shipped to the laboratory

Radium poisoning cannot be diagnosed from an examination of the blood Most of the profound anemias develop only in the terminal stages of the disease in individuals who have comparatively large radioactive deposits in their bodies Periodic blood examinations are of little value since small deposits may stimulate blood formation and blood counts of radioactive individuals be higher than those of the average industrial worker

The roentgenographic study of dental films for jaw necroses and the skeleton for evidence of radiation osteitis and malignancy is of great diagnostic importance in well advanced cases of radium poisoning

Treatment —No specific treatment so far advanced is of aid in long standing cases of radium poisoning especially those patients who show appreciable amounts of radioactivity and suffer from destructive bone lesions

In such cases extensive dental operations are contraindicated for they may result in intractable jaw necrosis When anemia develops therapeutic measures are of little value

In early cases long before clinical symptoms appear *decalcification therapy* consisting of a low calcium diet along with periodic administration of ammonium chloride parathyroid extracts and magnesium gluconate may be of some value for at this time the trabeculae of the bone contain some eleven times as much radium as the cortex and the radioactive substances are more accessible for mobilization and elimination

In older cases decalcification methods are of little value for the deposits are fixed in the cortex of the bone and the amount of radium excreted under this form of treatment is a very small fraction of the total stored radium

Prevention —No long lived radioactive substances in any form should ever be introduced in the human body because of the danger of radium poisoning

In industry all measures should be taken to eliminate or reduce to a minimum the swallowing of radioactive substances the inhalation of radon thoron or radioactive dust and external exposure to gamma radiation coming from large amounts of radium or from x rays

Such procedures should include the proper selection instruction and supervision

of personnel including cleanliness in the worker and work rooms forced ventilation of hoods and work rooms and other pre cautions

In addition, periodic medical and dental examinations including periodic radon or thoron analyses of the expired air and blood examinations for the detection of leuko penias anemias or any other abnormalities must be enforced

To protect the worker exposed to radium or other radioactive substances against radium poisoning and also any harmful ef fects from external noncumulative expo-sures to radium three important technical procedures should be carried out

1 To detect early minute radioactive deposits in the worker s body and to pre-vent further accumulations the *expired air* should be tested once a year or more often if necessary

When the radon analysis of the expired breath of any worker indicates the equiva lent of more than *0 1 of a microgram* of radium in his body (1 micro microcurie per liter of expired air) he should be removed from further exposure and treated by de calcification therapy or any other modality which may have been developed for this purpose

2 To avoid inhalation of dangerous amounts of emanation general forced ven tilation should be provided for all work rooms so that the radon concentration of the air does not exceed *10^{-11} curie per liter* at any place at any time Experience has shown that this is easily obtained in mod ern plants

3 To avoid undue exposure to gamma radiations coming from large amounts of radium in near vicinity of the worker it is important that the whole body exposure shall not exceed 0 1 roentgen per working day

THE INTOXICATIONS

ALCOHOLISM

Definition—Alcoholism denotes the state of the body following the ingestion of relatively large amounts of ethyl alcohol The sequelae of alcoholism depend on whether it is acute or chronic

Acute Alcoholism —*Definition* — The acute effects of alcohol depend primarily on its action on the central nervous system The definition of the state of drunkenness is difficult According to Purves Stewart a drunken person is one who has taken alcohol in sufficient quantity to poison the central nervous system producing a temporary disorder of the faculties so as to render him unable to execute the occupation in which he was engaged at the time thereby causing danger to himself or to others

Physiology—Alcohol is freely absorbed not only through the gastro intestinal canal but also through the lungs following inhalation It is quickly taken up after subcutaneous and intramuscular injection Alcohol is also freely absorbed from the rectum and the colon Thus severe intoxication may develop through accidental use of alcoholic solutions as in enemas Through the skin the absorption is slight unless there is inflammation or abrasion In the gastro intestinal tract slight absorption may occur even through the mucous membranes of the mouth A considerable degree of absorption takes place in the stomach and in the small intestines which readily absorb any alcohol that reaches them

The rate of intestinal absorption depends on the concentration of the ingested solution as well as on the intestinal contents The presence of food material particularly fatty substances delays absorption Habituation is apparently also a factor as it has been shown that absorption is more rapid in persons unaccustomed to drinking than in habitues

The distribution of alcohol in the tissues depends on the time interval between ingestion and analysis Following complete absorption distribution is fairly even in the tissues Concentration is high in the brain and low in the bones Alcohol has a caloric value of 7 calories per gram It is rapidly oxidized to carbon dioxide and water and it is estimated that in man between 5 and 10 Gm of alcohol are oxidized per hour At times some intermediary metabolite may appear in the blood The amount of excretion of alcohol depends on the intake but as high as 10 per cent may be eliminated in the urine sweat and other secretions Whether true tolerance occurs either in the form of increase in the oxidative capacity of the tissues or in the form of increased resistance of organs to the same amounts of alcohol is not definitely established

Following a single ingestion of alcohol the maximal level in the blood is fairly evenly maintained for about five hours The concentration of alcohol in the urine closely parallels that in the blood unless there is great delay between urine formation and emptying the bladder There is a rough correlation between the concentration in the blood and urine on the one hand and the clinical behavior on the other A concentration under 100 mg per 100 cc is generally not accompanied by symptoms Manifestations of exhilaration are usually associated with a concentration of from 100 to 300 mg and depression and severe ataxia with a level of 400 to 500 mg Above this level coma is frequently present A concentration of from 700 to 1000 mg usually causes death

Morbid Anatomy—When death is directly due to ethyl alcohol no specific gross or microscopic lesions are detectable Hence the cause of death cannot be determined from the morphologic findings Positive evidence can be established only through chemical analysis of the brain and other tissues The clinical history and postmortem findings nevertheless provide weighty indirect evidence There is usually an intense degree of postmortem lividity over the dependent portions of the body The mucous membrane of the stomach is frequently but not invariably congested or hyperemic and

punctiform hemorrhages or superficial erosions may be present The brain immediately after opening of the skull usually has a slightly aromatic odor Frequently there is some degree of edema of the pia arachnoid and of the parenchyma itself At present however no characteristic changes in the brain are known to exist Edema of the lungs occurs in many instances The right chambers of the heart may be distended The spleen liver and kidneys except for some congestion show no striking changes If cirrhosis of the liver is present this cannot be related to the acute use of alcohol

Symptoms—A small or a moderate amount of alcohol taken in the form of a beverage produces a general sensation of well being exhilaration and boosting of the ego This first stage of excitation depends primarily on removal of the inhibition of the higher centers After ingestion of larger amounts the functions of the higher centers become further disturbed and manifestations of depression of the central nervous system appear Judgment and capacity for observation become impaired and an increasing degree of euphoria develops Gradually reflex irritability is decreased and muscular incoordination develops If the consumption of alcohol continues sensory disturbances such as diplopia tinnitus aurium and numbness gradually appear The pupils often become dilated or in rare instances constricted and they may become unequal The face is generally flushed Frequently there is nausea and vomiting The pulse is full and the heart rate rapid The arterial pressure is somewhat lowered At this stage a marked degree of ataxia is usually present The subject may be unable to stand or even to sit up Gradual impairment of consciousness occurs often accompanied by incoherent muttering At times coma appears with unexpected rapidity The respiration is slow and stertorous and the breath smells strongly of alcohol or of the beverage consumed Circulatory collapse disturbance of heat regulation with lowered temperature acute urinary retention or incontinence of urine and feces may develop Such a degree of intoxication is dangerous and death may occur either with unexpected rapidity or following many hours of deep coma Severe reactions are enhanced by exposure to cold weather

In rare instances individuals who have taken moderate amounts of alcohol do not appear drunk but exhibit a type of automatism They may go about their daily work in an automatic fashion or they may wander away Frequently such individuals subsequently exhibit amnesia Their condition is called *alcoholic trance* or *alcoholic automatism* It depends primarily on psychic aberration of the patient and alcohol is merely a precipitating factor

Dipsomania is a special form of periodic acute alcoholism associated with emotional difficulties and maladjustment At times this tendency is inherited With an uncontrollable urge the subject goes on a spree Between attacks he is rather quiet and often subdued and exhibits no craving for alcohol Following the spree patients often experience intense remorse and depression They may attempt suicide Dipsomania is primarily a psychologic and social problem

Complications—Among the immediate complications of acute alcoholism are severe postalcoholic headache lassitude and dehydration Patients in alcoholic coma may subsequently develop lobar or bronchopneumonia from aspiration of food material or as a result of exposure If the coma is of long duration collapse and shock may supervene Following recovery some patients develop persistent vomiting which results in dehydration and circulatory collapse At times during forceful retching longitudinal lacerations at the junction of the esophagus and the cardia develop leading to severe and even fatal hemorrhage Jaundice caused by acute changes in the parenchyma of the liver at times follows alcoholic debauches Acute pancreatitis may develop secondarily and probably is related to vomiting and to regurgitation of intestinal contents in the pancreatic duct Nephritis may result from certain types of contaminations in the liquors Acute generalized distention of the abdomen imitating peritonitis or intestinal perforation and at times acute mania or convulsions can complicate the picture of intoxication Alcoholic intoxication is apt to bring to the surface underlying psychic abnormalities and conflicts If acute appendicitis or intestinal perforation occurs dur

ing alcoholic intoxication, it may give symptoms only when the patient has recovered from the alcoholic debauch

Among the complications of acute alcoholic intoxication mention should be made of its relation to exposure to venereal disease Finally acute alcoholism has an important bearing on the commitment of misdemeanor and crime Meyer states that in Massachusetts arrests for alcoholic intoxication in 1923 constituted 47 per cent of all arrests and in 1930 33 per cent

Diagnosis—This is usually not difficult if a history is available Nevertheless mistakes are not uncommon particularly with patients who are in coma The usual diagnostic errors involve fractured skull subdural or subarachnoid hemorrhage cerebrovascular accident uremia and diabetic coma Special caution should be exercised in diagnosing the condition of unknown patients brought to the hospital by the police In difficult cases, correct diagnosis will depend on the successful search for a history on a knowledge of the differential characteristics of coma of various etiology and on the laboratory findings

Prognosis—This depends on the amount of alcohol consumed and on the types of complications Acute alcoholic intoxication without coma usually disappears spontaneously The presence of coma however, offers a more serious prognosis Certain complications may seriously interfere with the recovery of the patient

Treatment—Usually no special treatment is required, as the subject sleeps off the intoxication Patients in alcoholic coma however require careful nursing supervision Gastric lavage should be performed promptly If the body temperature is subnormal and there are indications of collapse heat can be supplied effectively by irrigation of the stomach with warm saline solution The head should be lowered to prevent the aspiration of gastric contents Inhalation of a mixture of 5 or 10 per cent carbon dioxide and 95 or 90 per cent oxygen is effective in stimulating the respiration and hastens awakening Intramuscular administration of from 10 to 15 grains (0 75–1 Gm) of caffeine sodium benzoate or of a coffee enema will serve the same purpose Ephedrine sulfate administered intramuscularly in doses of ½ grain (30 mg) every two hours may be effective in awakening the patient The position of the body should be changed frequently in order to prevent hypostatic pneumonia In acute mania subcutaneous injections of apomorphine in doses of $\frac{1}{10}$ to ⅙ grain (6–10 mg) have been used effectively Apomorphine however can cause acute depression of certain vegetative nervous centers In the treatment of postalcoholic headache and dehydration fluids containing sodium chloride or mineral salt mixtures are useful

Chronic Alcoholism—*Definition*—A large number of persons who indulge in the chronic use of alcoholic beverages suffer from psychic and bodily consequences Persons given to this habit are nervously unstable and feel an irresistible urge to drink Since such an urge may arise entirely from disturbance of the psyche the medical problem of chronic alcoholism is primarily of psychiatric nature In spite of the fact however that the cause of chronic alcoholism is often psychogenic its consequences can be manifested in disturbances of numerous functions of the body Chronic alcoholism has also an important bearing on the clinical course of a number of diseases The various bodily effects produced by the frequent ingestion of moderate amounts of alcohol or by irregular bouts of drunkenness are collectively called "chronic alcoholism

Etiology—The immediate cause of chronic alcoholism is previous experience with acute intoxication Whereas some individuals go through such an experience without developing a special urge to repeat it others develop an addiction Many individuals suffering from chronic alcoholism exhibit unstable nervous systems and they are from a psychological point of view, inferior personalities Frequently the personality of the addict plays a more important role than the alcohol itself Chronic alcoholism is primarily a problem of psychiatry

Physiology—The immediate effects of the chronic ingestion of alcohol in the habitue are fundamentally the same as those produced by acute ingestion of nonhabituates There is some evidence indicating that the oxidation of alcohol may be more rapid in the chronic alcoholic Constant repetition of the same stimulus or insult may however

produce effects of far reaching consequences The chronic local effects of alcohol on the mucosa can lead to an inflammatory process (chronic gastritis) and this in turn may affect a number of digestive processes In view of the fact that alcoholic beverages are rich in calories but poor in vitamins and other essential food substances certain nutritional deficiencies are particularly apt to develop This tendency is further accentuated by the anorexia and gastric distress common in chronic alcoholics The demoralizing effect of constant conflict with society at large is also a factor that bears on the change in the nervous functions

Some of the manifestations attributed to chronic alcoholism are not due to ethyl alcohol but to admixture of substances such as ether acetaldehyde essential oils and lupulin of the hop The *convulsive seizure* observed following the chronic use of absinthe or vermouth probably depends on the action of oil of wormwood The adulteration of whisky with *triorthocresol phosphate* causes degeneration of the lower motor neurons with secondary chronic flaccid paralysis (*ginger or jake paralysis*)

The available statistics indicate that abstainers on the whole live longer than chronic alcoholics The fact that some chronic alcoholics may reach a ripe old age does not invalidate such a conclusion The Medical Research Council of Great Britain in a report published in 1923 concluded that the temperate consumption of alcoholic liquor may be considered to be physiologically harmless in the case of the large majority of normal adults that it is certainly true that alcoholic beverages are in *no way necessary for healthy life* that they are harmful or dangerous if 'certain precautions are not observed and that they are definitely injurious for most persons of unstable nervous system

Morbid Anatomy —The structural changes found on postmortem examination of chronic alcoholics are not specific or even characteristic They depend primarily on a high caloric intake Fatty infiltration or degeneration is observed in several organs particularly in the liver The heart may contain a considerable amount of fat over the epicardium Fatty infiltration and degeneration of the cardiac fibers may also occur There are no changes in the vessels which can be related to alcohol nor any evidence to indicate that the chronic use of alcohol causes arteriosclerosis The liver is usually enlarged and its at times remarkable increase in weight is due primarily to fatty infiltration and degeneration of the cells In some instances cirrhosis is superimposed The relationship between the chronic use of alcohol and advanced portal cirrhosis is not clear but it is certainly not a simple direct relationship Cirrhosis of the liver may be in some way related to certain types of nutritional deficiencies and to disturbances of intermediary metabolism The spleen too may show varying degrees of fibrosis depending on the amount of hepatic cirrhosis present In rare instances fibrosis of the pancreas or various grades of pancreatitis occur An atrophic type of gastritis is frequently encountered

The principal functional damage from the chronic use of alcohol is to the nervous system The mechanism of this effect is not clear It is not known whether the changes are due to an increase of fatty substances or to a lack of essential substances in the diet of chronic alcoholics Chronic leptomeningitis is frequently present as manifested by localized opaque and edematous areas When the edema is pronounced the condition is called wet brain or pia arachnoid edema These changes occur however in other diseases also Subdural hemorrhage (Virchow s pachymeningitis interna hemorrhagica) may result from trauma but seldom occurs spontaneously Presence of vitamin C deficiency may increase the tendency to traumatic subdural hemorrhage The *brain itself may be normal If it is* considerably reduced in size this is due to complicating arteriosclerosis or neurosyphilis Degenerative changes in the optic and peripheral nerves are found in a small group The nature of this finding is not clear but it is probably not due to alcohol itself It may be the result of chronic deficiency of essential food substances and in some instances the simultaneous use of nicotine also may be a factor

Symptoms —The abnormal manifestations exhibited by a chronic alcoholic patient can not always be attributed to alcohol Emotional instability and psychopathic tenden

cies are often present even *before* the chronic use of alcohol is established It should be remembered also that as the habit frequently lasts during a lifetime, numerous affections and diseases will develop independently

Nervous symptoms are common The mental processes may become dull particularly if the patient is unable to consume the accustomed amount of alcohol Often there is irritability and frequent loss of temper with outbursts of emotion fluctuating between rage and remorse Judgment may become impaired There may be progressive loss of muscular power associated with tremor of the hands and tongue In these persons who are rather over than undernourished, dilatation of the capillaries with resultant dilatation of the venules of the face (telangiectasis) frequently occurs Anorexia is often present partly as a result of chronic gastritis partly because of vitamin deficiency The fact that a large proportion of the caloric requirement is supplied by alcohol also plays a role Eructation and gastric and intestinal atony are frequent complaints Some of the digestive complaints are referable to an enlarged or a cirrhotic liver The presence of arteriosclerosis cannot be attributed to chronic alcoholism Similarly no chronic disease of the kidney is caused by alcohol Some of the contaminants or constituents of alcoholic beverages on the other hand exert an irritating effect on the kidneys The heart is affected by the chronic use of alcohol only so far as the resulting obesity can be associated with fatty degeneration of the heart In addition chronic alcoholic patients frequently do not eat and hence they are apt to develop beriberi heart nutritional edema pellagra and rarely scurvy

Chronic and excessive use of alcohol may undermine the constitution and lessen the resistance of the body to certain infections particularly to pneumonia The protective immunologic responses of the body seem to be impaired in chronic alcoholics but evidence is lacking that infectious diseases are more frequent in this group Whether chronic alcoholism exerts any specific unfavorable influence on the course of chronic tuberculosis is not definitely known

Diagnosis —When a history is available the diagnosis is not difficult In the absence of a history or if the condition is denied as is often the case particularly in female patients the manifestations may be puzzling Care should be exercised not to attribute all the symptoms of a chronic alcoholic to the use of alcohol As chronic alcoholism and luetic infection not infrequently coexist special study should be undertaken to rule out general paresis or other types of syphilitic involvement of the central nervous system

Prognosis —Permanent abstinence in chronic alcoholics is rare mainly because development of the habit depends on psychologic defects which in the course of prolonged use of alcohol become further accentuated

Treatment —No drug with specific benefit is known at present Successful treatment is possible only through proper analysis of the psychic difficulties of the sufferer In view of the fact that alcohol must not be consumed during such mental treatment and as most of the subjects are unreliable treatment should as far as possible be conducted in especially equipped institutions Sedatives and drugs with symptomatic benefit such as belladonna and amphetamine (benzedrine) may be used

The fundamental concept of the treatment of chronic alcoholism consists in attempts to improve the personal social or constitutional defects of the individual This can be achieved only through the cooperation of the patient Vacillations and doubts must be overcome by instillation of confidence and of convictions Past experiences and specific responses of the personality have to be taken into consideration Complete withdrawal of alcohol must be insisted upon Religious or other suggestive influences may be effectively utilized Cultivation of hobbies in chronic alcoholics may be helpful

Syndromes Related to Chronic Alcoholism —*Delirium Tremens* —This is an acute and usually transient psychosis observed often but not always after abstinence in persons chronically addicted to alcohol The condition does not develop in normal persons following acute intoxication Similarly it is not observed in chronic beer or wine drinkers In the history of patients suffering from delirium tremens heavy and often pro

longed debauch lack of food and sleeplessness frequently play a combined role Infections trauma and cardiac decompensation also may be precipitating factors The course is usually of two to ten days duration It is characterized by disorientation as to time and place by fear reactions the horrors' associated with visual or auditory hallucinations and by sensations of pain or paresthesias It is of interest that the content of these hallucinations may be the same in different attacks Visual hallucinations often take the form of small animals such as monkeys cats mice snakes or lice The onset may be gradual and the psychosis may be preceded by nervousness peevishness and restlessness Even during the active hallucination and disorientation the patient often retains his sensation of self and may enter actively into suggestions particularly in connection with the hallucinations Transitory rapport and mental clarity may appear Muttering and muscular tremor and incoordination are frequently present The delirium has many characteristics of an active vivid and changeable dream At times sudden fear reactions are accompanied by efforts to escape Paranoid trends may also dominate the clinical picture The delirium is usually worse at night The condition often clears up after a somewhat prolonged restful sleep Some of the manifestations of delirium tremens depend on the patient s fundamental make up and personality Persons with emotional difficulties are predisposed to delirium tremens Infectious diseases pneumonia in particular often precipitate the condition

The skin may be flushed or pale and is often covered with perspiration The pulse in young patients is high and bounding while in elderly subjects it is rapid and thready If the temperature is elevated it is of grave prognostic significance Albumin may be present in the urine Examination of the spinal fluid does not reveal any characteristic findings

PROGNOSIS —This depends on the severity of the reaction In cases with frank hallucinations the mortality rate is between 5 and 15 per cent Pneumonia and circulatory collapse are the usual immediate causes of death Fatal circulatory collapse can develop with unexpected rapidity

TREATMENT —No therapeutic measure is known at present to have a specific effect in delirium tremens The two most helpful measures consist in sedation and in proper feedings with concentrated food and with vitamin concentrates Large doses of sedatives and hypnotics should be given only under careful supervision as unexpected cumulative depression of the central nervous system and pulmonary edema frequently develop The patient should be kept in a comfortable position and should be disturbed as little as possible Oral or intravenous administration of 2 to 4 drachms of paraldehyde or of 10 to 30 grains (0 75–2 Gm) of chloral hydrate twice a day is frequently effective In milder cases 15 grains (1 Gm) of bromide three times daily may be helpful Barbiturates such as luminal in doses of 5 to 10 grains (0.3–0 75 Gm) are useful at times Frequently however the barbiturates accentuate the mental confusion Rarely hyoscine in doses of $\frac{1}{120}$ to $\frac{1}{60}$ grain (0.5–1 mg) may have a quieting effect Opium or its derivatives should be used with care Apomorphine is of doubtful value and may be harmful Strychnine is justified only as a measure in circulatory collapse It is given in subcutaneous doses of $\frac{1}{60}$ to $\frac{1}{30}$ grain (1–2 mg) In mildly delirious patients hydrotherapy may be effective Removal of adequate amounts of spinal fluid by lumbar puncture is at times useful

The water intake should be moderate, and part of this may be given in strong meat soups Concentrated foods with vitamin extracts administered every two or three hours also may be useful Nicotinic acid (or sodium nicotinate) in intramuscular doses of $\frac{1}{6}$ grain (10 mg) three times daily may clear up certain types of spastic muscular manifestations associated at times with delirium tremens If circulatory collapse is present this should be treated specifically

Korsakoff s Psychosis—This type of psychosis usually starts with delirium There is loss of memory but not of consciousness Frequently there is confabulation involving journeys or seeing certain persons The fabrication may appear reasonable and plausible at first The patient seems to feel constrained to yield to any suggestion made to him and to follow it with confabulation when fact fails The mental picture presented

by this condition may closely imitate that of delirium tremens Associated with the psychosis there are manifestations of polyneuritis and at times pellagroid skin lesions It is probable that in the etiology of this condition, just as in alcoholic polyneuritis nutritional deficiency particularly chronic deficiency of vitamin B plays a role

The TREATMENT is essentially the same as that of patients with delirium tremens but the prognosis is more serious Proper dietary measures are of particular importance Vitamin B concentrates or crystalline vitamin B_1 (thiamin) should be administered both orally and parenterally Parenteral administration of crystalline vitamin B_1 (20–40 mg) three times daily is indicated because intestinal permeability may be impaired Furthermore it improves the patient s appetite and makes possible subsequent effective oral feeding The use of nicotinic acid may be tried

Other Mental Manifestations—Chronic alcoholism may cause several additional types of mental disturbances particularly in individuals who have continued their drinking habits since early adult life The rate of incidence and the manifestations of these mental diseases depend primarily on the extent of the use of alcoholic beverages but they are also influenced by other factors In the United States the rate is higher among the foreign born than among the native population The nature of the acute mental manifestations seems to a certain extent to be determined by the innate personality of the patient Frequently the mental and neurologic syndromes overlap and a clear cut separation is impossible

Acute or Chronic Hallucinosis—In this condition hallucinations are mainly auditory in character The sensorium may be clear An *acute paranoid reaction* also occurs These patients become suspicious They develop jealous trends or persecutory ideas This reaction may be merely an accentuation of a 'normal submerged paranoid personality Some difficulty may be encountered in differentiating acute paranoid reaction from dementia praecox

Wet Brain—Chronic alcoholic patients often after several attacks of delirium tremens may suddenly fall into a semicomatose state associated with quiet muttering and delirium Their facial expression becomes fixed and staring Their tremulous hands make purposeless motions, grasping for objects or picking the bedclothes In contrast to delirium tremens this condition may run a prolonged course though sudden death due to circulatory collapse is not infrequent If recovery occurs this is rather slow and unless forced feeding is undertaken a marked degree of emaciation may develop

TREATMENT *consists mainly in careful* nursing taking precautions to avoid aspiration pneumonia and in adequate feeding Forced feeding through a nasal tube may have to be instituted Dehydration should be prevented by the administration of fluids through the channels indicated

Alcoholic Deterioration—This is a slowly developing change of the personality Patients suffering from this condition frequently maintain a fairly good insight They are rather carefree irresponsible and jovial Often they are easily influenced and their activities lead to conflicts with the social and moral codes Their capacity to do physical work becomes seriously impaired

Neuritis—This condition was described classically in 1822 by James Jackson Sr It is probably due to a vitamin B deficiency rather than to excessive use of alcohol but the latter plays more than an indirect role It occurs among steady drinkers The onset depending on the intensity of the drinking may be gradual with annoying paresthesias of the hands and feet or it may be rapid with motor manifestations Motor paralysis is apt to involve the feet legs hands and arms but not necessarily symmetrically The extensors of the feet are frequently affected and their involvement may last longer than that of other muscles giving a characteristic steppage gait In some instances difficulty may develop in the function of the sphincters of the bladder and rectum indicating cord involvement The complaints are at times due entirely to sensory disturbances as manifested by persistent severe pain or burning sensation Tachycardia is a frequent manifestation (*vagus neuritis*) Mental symptoms with hallucinations may complicate the picture (*Korsakoff s psychosis*)

The clinical characteristics and the eti

ology of this type of polyneuritis are quite similar to if not identical with those occurring in beriberi not associated with the use of alcohol The condition may persist for weeks or months but under proper treatment it ultimately clears up Not infrequently the clinical picture of polyneuritis is complicated by manifestations of *pellagra* including glossitis achlorhydria and diarrhea Some of the patients exhibit *nutritional edema* and cardiac decompensation (*beriberi heart*) with normal sized or with enlarged heart *Optic* and *retrobulbar neuritis* may develop without peripheral neuritis This lesion is usually attributed to methyl alcohol but its etiology is the same as that of alcoholic polyneuritis Nicotine may be a contributory factor

TREATMENT consists in withdrawal of alcohol and administration of a highly nutritional diet particularly rich in vitamins Vitamin B concentrates should be given by mouth and parenterally Of crystalline vitamin B_1 (thiamin) doses of 100 mg or more may be administered intramuscularly or intravenously every day Liver extracts are particularly beneficial if lesions of pellagra are present Massage of the extremities and physiotherapy should be given Smoking should be eliminated

METHYL (WOOD) ALCOHOL POISONING

Definition and Etiology—This intoxication is usually caused by the use of adulterated beverages containing methyl alcohol Accidental and industrial poisoning also occurs Methyl alcohol may be absorbed through the skin after a local application or poisoning may result from inhalation Methyl alcohol is somewhat more toxic than ethyl alcohol It is less readily oxidized and if its oxidation is incomplete formic acid is produced which may be responsible for acidosis A large percentage of methyl alcohol is eliminated in the urine Its chronic use is particularly harmful

Symptoms—Gastro-intestinal disturbances such as epigastric or abdominal pain nausea and vomiting and obstinate constipation may indicate the onset of intoxication Weakness dizziness vertigo and headaches may precede delirium coma and unconsciousness Nystagmus dilated pupils dyspnea and cyanosis are also frequent features The dyspnea may be severe and associated with intense thirst The coma is considerably more prolonged than that following an equal dose of ethyl alcohol The estimated fatal dose is between 100 and 250 cc but marked variations in individual susceptibility exist Death may occur suddenly either soon after the intoxication or following several days of coma Repeated ingestion of methyl alcohol leads to lassitude mental deterioration and delirium

One of the dreaded neurologic effects is *optic neuritis* This is usually bilateral It may start with dimness of vision and scotoma and may progress slowly or rapidly to complete blindness Blindness may develop within a few days Some improvement may occur subsequently

Treatment—This should consist in effective measures for the elimination of methyl alcohol Gastric lavage should be performed at once and 1 ounce of Epsom salts should be left in the stomach Lavage of the colon should be performed three times a day Dehydration should be prevented and circulatory collapse should be treated by appropriate measures

BARBITURATE INTOXICATON

The barbituric acid derivatives are by far the most widely used sedatives and hypnotics Accidental and unintentional intoxication with barbiturates has become common and suicides are frequently committed with these drugs Their widespread use is due partly to their frequent prescription by physicians but also to the fact that they can be freely purchased without a medical

order If morphine and cocaine addicts are unable to procure the drugs to which they are addicted they often resort to the use of large doses of barbiturates Since the introduction of barbital into clinical medicine, a long series of barbituric acid derivatives have appeared under various trade names The action of all the members of the group is quite similar, the most essential difference being in the duration of effect Allonal, amytal barbital dial evipal gardenal ipral luminal medinal nembutal noctal pentobarbital pernocton phenobarbital and veronal are some of the more frequently used members of the barbiturate group of hypnotics

Acute Intoxication—This may be the result of individual susceptibility to a therapeutic dose or may occur following accidental or intentional consumption of a large amount of the drug Persons in depressed nervous states are susceptible to the barbiturates

Physiology—The barbiturates are taken up rather diffusely by all parts of the brain as well as by tissues of other organs The effects depend primarily on their action on the brain stem This does not however indicate that the vegetative centers of the brain stem combine with a relatively large amount of barbiturates but rather that the functions of the midbrain centers are particularly susceptible to the chemical action of these drugs There are no detectable structural changes in the central nervous system following acute poisoning

Symptoms—These vary with the amount of the drug taken as well as with the channel of administration When absorption is gradual confusion a dull sensation in the head and ataxia may be the first manifestations Subsequently impairment of the sense of smell and of taste and difficulty in swallowing occur Nausea vomiting generalized excitement and hallucinations may precede the onset of sleep This sensory or motor excitement varies with different barbiturates In the early stage of sleep the respiration is of the Cheyne-Stokes type subsequently it becomes rapid and regular The heart rate and blood pressure remain essentially unaltered in the early stage Subsequently circulatory collapse is apt to appear Cyanosis moist skin and the appearance of congestive rales over dependent portions of the lungs are grave signs The pupillary and deep reflexes are usually maintained for a relatively long time in coma but the presence of Babinski and abdominal reflex responses indicates disturbances in the function of the pyramidal tracts Death may be caused by direct paralysis of the respiratory center but more frequently it is due to vasomotor collapse and secondary bronchopneumonia

Diagnosis—The presence of coma with quiet regular respiration in subjects in whom drug intoxication is suspected should raise the possibility of barbiturate poisoning A definite diagnosis can be established only with the aid of a proper history and of chemical tests

Prognosis—The course of barbiturate poisoning is treacherous Death may occur even several days after the ingestion of the drug Pneumonia may prove fatal after the patient has recovered from the immediate effects of poisoning

Treatment—If the intoxication is mild withdrawal of the drug relieves the patient In cases of severe intoxication gastric lavage should be performed promptly with a warm solution of permanganate or warm saline solution Before the removal of the tube from 30 to 60 Gm (1–2 ounces) of magnesium sulfate in 50 per cent solution should be instilled into the stomach Strychnine in doses of 5 mg (1/12 grain) or more may be given intramuscularly or intravenously every two hours The dose should be reduced as the general condition of the patient improves Picrotoxine in doses of 0 5 to 1 mg (1/120–1/60 grain) administered intramuscularly every two to six hours depending on the condition of the patient is an effective remedy Ephedrine in amounts of from 20 to 30 mg (1/3–1/2 grain) or benzedrine in doses of from 10 to 15 mg (1/6–1/4 grain) at two hour intervals may be useful in arousing the patient If cyanosis and respiratory disturbances are present inhalation of a mixture of 5 or 10 per cent carbon dioxide and 95 or 90 per cent oxygen is indicated Coramine may give temporary relief but if the respiration does not show a tendency to improve a respirator should be used

Chronic Intoxication ("Barbiturism")—This is quite a frequent occurrence It plays a more important role in medicine to

day than cocainism although it bears quite a different significance Barbiturism develops as the result of prolonged and careless use of these hypnotics through medical prescription or as a household remedy Not infrequently it occurs among drug addicts who have resorted to barbiturates as a substitute for morphine heroin or cocaine Barbiturism is not associated with withdrawal symptoms Tolerance is not formed

Physiology—The effect of the chronic use of these drugs depends on chronic intoxication of the nervous system and depression of vegetative functions Degenerative changes in the nerve cells have been observed in animals following prolonged administration of the barbiturates

Symptoms—Gradual loss of ambition impairment of capacity for concentration and an increasing desire to sleep particularly after meals are the most common manifestations Vertigo ataxia, nystagmus visual hallucinations difficulty with accommodation and with the function of ocular muscles squint thick or anarthrous speech ataxia or paralysis of the limbs may develop Failing of memory with slowness of thought is sometimes experienced Changes in the reflexes either suppression or accentuation and the appearance of pyramidal signs may further complicate the puzzling clinical picture Albumin and casts may appear in the urine and hematoporphyrinuria is a rare complication

Diagnosis—Chronic barbiturate poisoning presents a variable and often puzzling clinical picture and the diagnosis may be exceedingly difficult if a history is not available The manifestations may imitate those of encephalitis lethargica acute psychic depression pseudobulbar palsy general paresis or delirium tremens

Prognosis—This is usually favorable

Treatment—Chronic intoxication requires only the withdrawal of the drug If mental problems are present they should be managed with psychotherapeutic methods

OPIUM INTOXICATION

The clinical significance of opium intoxication depends on whether it occurs in its acute or its chronic form The taking of toxic doses with suicidal intent or accidentally in the course of medication is a common cause of acute intoxication The chronic opium addict who is in the tolerant state never suffers from acute opium poisoning but severe poisoning and even death frequently occurs among opium addicts who have lost tolerance to the drug by a few weeks of abstinence Followng a half hearted or forced cure many of these cases ignorantly take the size of dose to which they had been accustomed when tolerant but which is now poisonous to them

LAWRENCE KOLB

ACUTE OPIUM INTOXICATION

The symptoms of acute intoxication are essentially the same regardless of whether opium or one of its derivatives such as morphine dilaudid or heroin is the causative agent Flushing of the face giddiness lassitude and incoordination first occur drowsiness quickly follows the skin becomes pale respiration and pulse are slowed and the pupils contracted Nausea and vomiting may be early symptoms Following large doses somnolence rapidly deepens into sleep and coma from which the patient can be roused in the early stages As coma deepens he cannot be roused the reflexes disappear the temperature falls the pupils become pin point the pulse may become irregular and feeble and cyanosis develops Respirations are always depressed and may be reduced to a few gasps per minute Cheyne-Stokes type of respiration is common Asphyxial convulsions more common in infants may occur in the late stage Edema of the lungs is common in this stage but not necessarily fatal Dilatation of the pupils is of grave prognostic significance Recovery may occur in patients so severely poisoned that they are in deep coma and are breathing only two or three times per minute The combination of cyanosis dilated pupils and pulmonary edema is always fatal Patients with pulmonary edema may awaken from coma show improved respiration and then die four or five

hours later, *apparently from progressive* weakness of the heart and the edema In recovery the pulse gradually improves and the coma changes to a prolonged deep sleep which may last for several hours or even a day or two Headache mental depression vomiting itching of the skin and difficulty in initiating micturition follow intoxication This latter symptom may also be present during the more acute stages of intoxication, and calls for attention and treatment Some persons may develop maniacal excitement and, on rare occasions convulsions following the medicinal use of morphine or codeine and patients with severe anemia and hepatic *insufficiency are thought to be particularly* susceptible to the depressant action of morphine Infants are highly susceptible to opiates Myxedematous patients may be put into deep coma by ¼ grain (0 016 Gm) of morphine

Diagnosis—The history of the medicinal or other use of narcotics together with the clinical picture is usually sufficient to establish the diagnosis Pin point pupils though not specific for opium poisoning help to differentiate the condition from alcoholic coma The gradual development of coma together with the depression of respiration as low as eight or ten per minute, is highly suggestive of opium poisoning In doubtful cases an examination of the urine may disclose the presence of morphine

Treatment—Treatment consists in efforts to remove the drug from the gastro intestinal tract if the opium has been taken by mouth to stimulate respiration and to prevent circulatory collapse Gastric lavage should be performed promptly with several liters of potassium permanganate (1 to 5000) Lavage should be performed through a nasal tube as lavage by the ordinary stomach tube increases the tendency to coma and to edema of the lungs The best chemical antidote is charcoal After lavage 50 cc of 20 per cent charcoal suspension should be *introduced* together with 50 cc of 50 per cent magnesium sulfate solution Repeated gastric lavage for the removal of morphine excreted in the stomach is of doubtful value and may be harmful Edema and bronchopneumonia have been produced by it The patient should be covered warmly He should be kept awake by reflex stimulation such as the inhalation of ammonia in the form of smelling salts and cold ablutions to the skin Walking the patient around to keep him awake is probably harmful in view of fatigue The greatest danger is from respiratory collapse Hot strong coffee and small doses of caffeine are good respiratory stimulants The administration of 10 per cent carbon dioxide and 90 per cent oxygen is also effective The patient may have to be placed in a respirator Coramine and metrazol are the best respiratory stimulants, and of these two coramine is preferable as it is less likely to cause convulsions in persons poisoned by opium To a patient in coma *5 cc of 25 per cent solution of coramine* should be given intravenously A deeply comatose patient breathing only a few times per minute may be awakened and the respiration greatly improved by this treatment, but in serious cases the treatment has to be repeated several times at intervals of a few minutes If drowsiness sets in again after a few hours a new injection may be given intramuscularly Failure of the heart evidenced by tachycardia and wheezing of the lungs should be combated by the intravenous administration of digitalis If great restlessness or convulsions occur from the use of coramine 15 grains (1 Gm) of chloral hydrate in solution should be given by rectum A common effect of severe opium poisoning is bronchopneumonia Sodium sulfadiazine 1 Gm dissolved in 20 cc of water administered every four hours intravenously until the patient can swallow, is said to be an effective preventive Sulfadiazine should be continued for twenty four hours after the subsidence of the coma

LAWRENCE KOLB

CHRONIC OPIUM INTOXICATION (OPIUM ADDICTION)

Opium addiction is a physiologic condition of tolerance to and dependence upon opium brought about by the continued use of some drug of the opium series usually in increasing doses Tolerance may be built up to increasing doses of many drugs but opium is the only drug that produces dependence Dependence is the most striking characteristic of addiction and is what most people have in mind when they speak of opium addic

tion but the most potent causes of continued chronic addiction to opium are psychologic The habitual user of morphine the most important opium derivative can in about nine months build up a tolerance to 60 grains (4 Gm) per day an amount sufficient to kill or seriously poison about fifteen unaddicted adults but instead of being killed or seriously harmed by this large dose the addict suffers intensely and may even die in collapse if it is abruptly taken from him

The limit of tolerance is not known Addicts have been known to take an ounce of morphine in a week and experimentally a strongly habituated morphine addict has been given 20 grains (1.3 Gm) of morphine sulfate intravenously within an hour with only mild discomfort and no signs whatever of collapse

With unrestricted access to the drug the average addict will take about 15 grains (1 Gm)of morphine daily Doses vary with the degree of normality of the individual Normal people tend to stabilize the dose while psychopaths are prone to increase it A few nervously normal individuals get along on a grain or two a day while the extreme psychopaths may require from 30 to 60 grains (2 to 4 Gm) to satisfy their craving Because of the scarcity of opiates in the illegitimate market at the present time the average daily dose of addicts who are supplied by *narcotic peddlers is probably not* more than 1 or 2 grains (0 06 to 0 13 Gm) of morphine This may be fraudulently diluted so that the product that he actually buys contains as little as 5 or 10 per cent of morphine

Under the influence of necessity or for experimental purposes addicts shift from one opiate to another with only a slight feeling that something is different However adjustment is made in a week or two The morphine addict who shifts to heroin does not reduce the daily dose He apparently requires at least an equal amount of heroin to satisfy the physical dependence built up by morphine

Any preparation of opium that relieves pain will bring about physical addiction in anyone who uses it continuously in increasing doses but addiction to codeine is extremely rare apparently because codeine does not produce euphoria

In the Orient eating and smoking opium are methods of choice among addicts but the alkaloids have been introduced in recent years and their use is growing In the United States the use of such preparations as laudanum and powered opium was once fairly common among addicts, but at the present time the concentrated preparations such as morphine heroin and dilaudid are used almost exclusively except among the Chinese residents who still persist in smoking The alkaloids are usually taken hypodermically or intravenously Heroin was at one time used extensively by snuffing but the product now available in the illegal market is diluted too much to be effective as a snuff

Smoking is the least harmful form of addiction The hypodermic or intravenous administration of the alkaloids is the most harmful A reason for this is that addicts who use the alkaloids this way quickly build up tolerance to large doses Most addicts in the United States use morphine hypodermically A large proportion of the psychopathic group inject morphine or heroin intravenously Such weak preparations as paregoric may be taken by mouth when the alkaloids are not available

Etiology.—The cause of addiction depends in a measure upon the setting in which it occurs From the standpoint of origin addicts may be divided into two classes (1) Pure dissipators and (2) those whose addiction resulted from medication The dissipators accidentally find that opiates have an agreeable effect upon them and become addicted through their quest of this effect In medical cases the patients become addicted through the prescribing of physicians or by self medication for some disease for which an opiate is apparently indicated Addicts may be further divided into the nervously normal and the nervously abnormal Among the latter are many who were introduced to the drug through medication The nervously abnormal group comprises persons suffering from various forms of deviated personalities including psychopathic psychoneurotic and psychotic individuals and persons with inebriate personalities Opiates are used by these various abnormal groups as a method of solving their problems The narcotizing effect of these drugs is for them a more or less satisfactory form

of adjustment of which they have accidentally become aware The nervous pathology of these types whether due to heredity or environment or to both is by far the most important cause of their continued addiction These unstable individuals whether originally addicted through dissipation or by medical means have feelings of inferiority restlessness and discontent which under the influence of opiates, are replaced by confidence calmness and contentment The degree of contrast with their usual selves is in direct proportion to their deviation from the normal It amounts to intense pleasure in some psychopathic cases, but it wanes as tolerance is established and is finally lost altogether Efforts to recapture that pleasure in the original form account for the enormous doses that some addicts build up to and memory of it is a potent cause for their relapse after cure

Individuals comprising the normal group usually get well promptly when the reason for the medication is removed hence such individuals are rare among chronic addicts A study made in 1925 showed that 14 per cent of chronic addicts belonged to this class A study made at the Public Health Service Hospital at Lexington Ky in 1938 showed that only 3 8 per cent of the addicts there had normal nervous constitutions Among the abnormal group are a large number of carefree individuals devoted to pleasure seeking new excitements and sensations and usually having some ill defined instability of personality that often expresses itself in mild infractions of social customs These mildly psychopathic individuals make up the largest percentage of addicts There is a smaller group of more abnormal psychopaths and a still smaller group of psychotics The inebriates comprised approximately 21 5 per cent of two large groups of addicts that have been carefully studied Addicts of the inebriate type are probably closely related to the psychoneurotics A distinguishing feature is that they have a periodic impulse to drink and usually become addicted to opiates through taking them in the form of morphine to sober up from the sprees After cure members of the inebriate group have a strong tendency to relapse by the alcohol route They take alcohol in order to satisfy an indefinite craving characteristic of them and when inhibited by it they recklessly take morphine again Some acquire a questionable cure of the morphine habit by becoming chronic alcoholics There are a few psychotic addicts but opium plays only a very minor causative role if any in these cases On the contrary, it is probable that the habitual use of it by easing stresses in predisposed individuals saves some from breaking down into frank psychosis

Morbid Anatomy—The chronic opium addict is usually a pale anemic malnourished individual The arms shoulders buttocks legs and even the trunk of many of them are covered by scars of old abscesses produced by the use of dirty needles Similar scars may result from abscesses due to the injection of cocaine but the cocaine addict who reaches the abscess stage is practically always also a morphine addict Other than the abscess scars there is no proved morbid anatomy due to chronic opium intoxication Degenerative changes in the brain spinal cord heart liver and kidneys have been reported in association with it but in all probability these changes have been due to associated diseases malnutrition or vitamin deficiency so common among addicts

Physiologic and Psychologic Effects.—Minor physiologic changes occur in the course of opium addiction These changes are apparently associated with the adjustment incident to tolerance The mechanism of tolerance is not understood Among the recorded changes is a tendency to a low red cell count and a high leukocyte count The blood cholesterol is usually increased The lactic acid is uniformly high and the specific gravity of the blood is lower than normal The brain potentials show an increased alpha output in sustained addiction

After a few weeks of abstinence from opiates patients appear to have recovered physically but there is not complete readjustment of all physiologic processes for several months The basal metabolic rate and the level of inorganic phosphorus in the blood are subnormal as late as the sixth month after the last dose is taken The libido is markedly reduced or abolished in men and the menses in women by large doses (15 to 30 grains [1 to 2 Gm] of morphine daily) Both promptly return on withdrawal of the drug Sterility never results

The death rate among addicts is much higher than in the general population This is in part due to the fact that a large proportion of addicts are already diseased when they contract the habit The difficulties that they have in maintaining addiction in a hostile environment is also important They are alternately sick from forced abstinence and lethargic from eager overindulgence when the needed drug is obtained General vitality is therefore lowered and is often still further decreased by malnutrition Abscesses and tetanus contracted by the use of soiled needles and malaria and syphilis from the use of common needles passed from addict to addict add to the toll

The effect of opiate addiction on personality and character is confused Much of what is regarded as evidence of moral deterioration is really original psychopathology plus difficulties placed in the way of the individual by society Many drunkards who become opium addicts are improved morally physically and socially by the change Some shrinking individuals are made more efficient by small doses of opiates that tend to blot out their sense of inferiority Nevertheless continued addiction has some deleterious effects on character The secrecy of the habit the practice of evading issues and of solving difficulties by blotting them out through the use of narcotics the parasitic lives that so many addicts are compelled to live the conflict with the law, the poverty and malnutrition that result from the spending of so much money to secure needed narcotics in the illegitimate market tend to bring about physical and moral deterioration but intelligence is not impaired and psychoses do not occur except rarely as acute episodes on withdrawal of the drug from highly susceptible individuals Character deterioration is greater in opium addicts who were much below par in the beginning than in those who had social responses and habits approaching normal The chief crime committed by opium addicts is violation of narcotic laws Many rob and steal to get the drug and some indulge in confidence games Because of the soothing effect of all addicting opiates violent crime among addicts is rare The nervously normal addict who regularly secures a sufficient supply of drug for his physical needs shows no deterioration in morals or in social and intellectual activities An 81 year-old normal mother of six healthy children took 3 grains (0 2 Gm) of morphine daily for 65 years Similar instances are not uncommon

Children born of addicted mothers are as a rule healthy but in cases where 20 or 30 grains (1.3 to 2 Gm) of morphine per day have been taken the newly born infant may show withdrawal symptoms which need treatment

Withdrawal Symptoms (Abstinence Syndrome) —The withdrawal of opiates from persons habituated to their use is followed by a train of severe symptoms The intensity depends upon the duration of the addiction the size of the accustomed dose and the rapidity of the withdrawal These symptoms are dreaded by addicts Added to the immediate discomfort is the fear of death that some of them have during the most intense phase of withdrawal The symptoms represent the 'running wild of functions that had learned to operate normally under the tremendous check that opium had put on the nervous system It is as if the fly wheel had been removed from an engine and some patients describe the situation by saying that they feel as if they would fly to pieces

The drug is missed always about eight hours after the last dose Restlessness and a feeling of nervousness then occur From then on there is a gradual development of symptoms with yawning lacrimation rhinorrhea perspiration goose flesh hot flashes chills loss of appetite mydriasis tremors and twitching of muscles Insomnia may be distressing Vomiting and diarrhea may be so severe as to dehydrate the patient and cause considerable loss of weight Pains in the abdomen and legs are common

Measurable signs that invariably occur are increased respiratory rate rise in temperature and blood pressure and increase in blood sugar and in the basal metabolic rate Wide dilatation of the pupils associated with thready pulse and irregular respiration is a danger sign Death presumably from circulatory collapse occasionally occurs Some patients become excited while others are depressed during withdrawal and mild psychotic episodes occur in rare cases The symptoms reach the maximum of se-

verity in about 48 hours and then gradually decline About four or five days after the last dose of morphine the patient feels reasonably comfortable and in two weeks there are no striking physical symptoms except insomnia which may distress him for several months The recovery in young men is rapid After two weeks they may feel nothing of a distressing nature except insomnia Addicts past fifty may feel lethargic and depressed for two months or more

Diagnosis—Diagnosis presents no difficulty as a rule because the average patient readily admits his addiction The underworld type of patient is usually pale owing to anemia and many of them have characteristic cutaneous scars due to needle abscesses or dark lines along the course of veins that have been used for injections Addicts who have been able to sustain themselves with sufficient food and who are clean in their habits may show absolutely nothing with the possible exception of a fresh needle mark at the point of a recent injection The pupils are normal during sustained addiction Isolation brings out withdrawal symptoms together with an admission that what is needed is an opiate Morphine can be detected in the urine for about four days after the last dose has been taken and in doubtful cases an examination of the urine may clear up the diagnosis

Treatment—The treatment of a case of drug addiction in a person with a normal nervous constitution and no painful physical disease presents no great difficulty Persons with abnormal personalities or with physical disease present more serious problems because they are prone to change their minds about the necessity of treatment before withdrawal is completed and are very prone to relapse shortly afterwards There is no specific remedy for the treatment of withdrawal symptoms The essential thing is to deprive the patient of the drug as painlessly and as harmlessly as possible Many empirical methods for doing this have been devised Some of them are harmful and have contributed to the death of patients in withdrawal Treatment with large doses of toxic drugs and extreme purgation should be especially avoided Abrupt withdrawal is one of the least harmful of the objectionable methods It is widely used in prisons and is effective, but it leaves psychologic scars that contribute to relapse Abrupt withdrawal combined with a few doses of codeine may be used without harmful effects physical or psychologic, in patients who have a very mild addiction

Treatment can be carried on at home and many addicts, even of the relapsing type have successfully carried themselves through the withdrawal period at home without the help of a physician, but the management of an addict at home is usually not satisfactory Preferably treatment should be carried on in a hospital in which the environment can be controlled The approach to the patient should be made, however, with an eye to his psychologic adjustment, because this is most important for continued cure The patient should be stabilized on from 1 to 4 grains (0 016 to 0 06 Gm) of morphine daily in four equally divided doses depending upon the degree of his addiction for two to four days before withdrawal is attempted Withdrawal should then be made rapidly in accordance with a fixed schedule of opiate medication It should be effected in from four to ten days, depending upon the severity of the addiction and the physical condition of the patient

The schedule has to be varied with the patient but temporizing with him by the administration of morphine beyond the scheduled period or in increased amounts is seldom justified A good schedule is as follows For a patient who has been stabilized on 4 grains (0 26 Gm) of morphine daily give 1/4 grain (0 016 Gm) of morphine four times per day on the first day Give 1/8 grain (0 008 Gm) of morphine four times per day on the second day and two 1/8 grain (0 008 Gm) doses at twelve-hour intervals on the third day After this codeine should be substituted for morphine on a similar schedule for three days longer Give 15 grains (1 Gm) of bromide three times per day beginning on the second day to reduce intense nervousness and restlessness Larger doses of bromide up to 60 grains (4 Gm) three times per day may be given but in no case should administration be continued more than three days because of the danger of bromide intoxication

The insomnia responds better to paraldehyde than to other

turates especially have been found to cause confusion and delirium and to increase restlessness in some addicts undergoing withdrawal After a low cleansing enema 10 to 15 cc of paraldehyde in warm olive or cotton seed oil should be given by rectum before bedtime for several days beginning on the second day of treatment Diarrhea may be troublesome for the first two or three days It should be controlled when necessary by 15 grains (1 Gm) of bismuth subcarbonate three times daily If at the beginning of treatment the patient is constipated an enema should be given Two ten minute flow baths per day should be given during the period of actual withdrawal to reduce restlessness and relieve aches and pains in the legs and back The temperature of the water should be gradually increased from 98° to 104° F (36 7° to 40° C) and the patient should be carefully watched for rapid pulse and complaints of faintness If these occur he should be promptly removed from the bath Aspirin 5 grains (0.3 Gm) every two or three hours reduces the intensity of aches and pains Intravenous infusions reduce restlessness and restore fluid and salt loss One thousand cc of 0 85 per cent NaCl or Ringer s solution should be given in the morning and 1000 cc of 5 per cent aqueous solution of dextrose in the evening

The patient should be encouraged to eat during the entire withdrawal period He may not be able to tolerate anything except liquids such as eggnog milk and fruit juices during the first two or three days however It is not necessary or desirable to keep him in bed against his will He should stay in the hospital under supervision for at least two or three weeks and preferably for several months after withdrawal Sedatives and hypnotics should be used sparingly if at all during this period As a rule they should be discontinued two or three days after the actual withdrawal of the opiate The addict who leaves the hospital with advice to take such drugs usually overdoses himself with them and quickly relapses to the original opiate

When possible psychotherapy and constructive work preferably out of doors should be continued for two or three months after the actual withdrawal This treatment by ventilating the patient s original difficulties, building him up physically and establishing new habit patterns tends to give him a new outlook on life and fortify him against relapse

Relapse is common in any event in the nervously unstable and in persons suffering with such physical conditions as asthma migraine and neuritis Among the unstable the fundamental cause is identical with that which led them into the original addiction Physical disease seductive memory of past pleasant experiences with narcotics conditioned memory association indulgence in alcohol and a hostile environment contribute to it As with the chronic alcoholics many relapses may eventually be followed by permanent cure

COCAINE INTOXICATION

(*Acute Intoxication*)

Acute cocaine poisoning is fairly common It occurs as a rule in persons in whom the drug is used as a local anesthetic Poisoning

from throat and nasal sprays in which co caine was used was once common Unlike opium addiction a rare case of acute cocaine poisoning may occur in an active cocaine ad dict Accidents are due to excessive doses mistakenly given or to faulty technic Susceptibility to the drug varies greatly owing to individual idiosyncrasies and dif ferences in the rate of absorption The addi tion of epinephrine to cocaine injections reduces the toxicity and increases the an esthetic effect chiefly by delaying absorp tion but epinephrine makes some hyper sensitive individuals more susceptible to cocaine collapse Death has resulted from ⅓ grain (0 02 Gm) of cocaine and serious poi soning has occurred from much smaller doses The danger is much greater when con centrated solutions are used Less dangerous drugs have largely superseded the use of cocaine as a local anesthetic

Symptoms—The symptoms in cocaine poisoning are similar to those due to the syn thetic substitutes procaine butyn and so on In mild intoxication resulting from slow absorption or small doses there may be ex-citement pleasurable or disagreeable the pa-tient is restless more garrulous than normal, and often anxious and confused Along with these symptoms there may be laughter ver tigo rapid pulse and irregular respiration *Larger doses cause a feeling of faintness to* gether with pallor sweating rise of tempera ture dilated pupils dyspnea, Cheyne Stokes respiration tremors and mild convulsive twitchings that may go on to tonic or clonic convulsions Death may occur from cessation of respiration during a convulsion In most of the fatal cases convulsions are absent but collapse quickly occurs apparently from rapid absorption If the patient lives a few minutes after the toxic dose has been taken he almost always recovers

Treatment—Treatment should begin with *prevention Careful attention to the* preparation and dosage guards against errors that have caused many deaths If idiosyncrasy is feared the previous admin istration of a barbiturate adds a margin of safety by suppressing convulsions and pre-venting their interference with respiration When an overdose has been taken the pa tient should be placed in the shock position If the drug was taken by mouth the stom ach should be emptied immediately Sodium luminal 5 to 10 grains (0 3 to 0 75 Gm) should be given intravenously to prevent or suppress convulsions as indicated Sodium amytal is also effective Artificial respiration should be instituted if necessary

CHRONIC COCAINE INTOXICATION

A mild form of chronic addiction to co caine has occurred for centuries among the Indians in the west of South America espe cially in Peru and Bolivia Many of the na tives believe that by chewing the coca leaves they will be able to do more physical work with less fatigue and without feeling the pangs of hunger and thirst Many of them use the drug regularly however and with reported deleterious effects on both physical and mental health In the United States cocaine addiction is now extremely rare and never has been common as a continuing ad diction There were only seven cases among 150 addicts studied in 1924 Among the first 3000 admissions to the United States Public Health Service Hospital at Lexington Ky which was opened in 1935 for the treatment of narcotic addicts there was only one case of cocainism Mixed cocaine opiate addiction *has been quite common* in the past but is also decreasing There was not one case of pure cocaine addiction in a series of 210 cases studied in 1927 but 35 per cent of the total number had been addicted to both cocaine and an opiate at one time or another A number of persons dissipate with cocaine now and then but never become *addicts* Their indulgence is comparable to week end drinking

Etiology—Instability of personality is of the same importance in the causation of chronic cocaine addiction as in opium addic tion but unlike opium addiction physical dependence is not a factor In cocaine addic-tion there are no distressing withdrawal symptoms The anesthetic properties of co caine were discovered in 1884 and from then until the Harrison Narcotic Law was en acted in 1914 the drug was widely used in this country in *sprays for* asthma hay fever and throat infections Many cases of addic tion resulted from this medicinal use of co

caine but the most common cause of addiction has been dissipation Use of the drug is begun out of curiosity and it is continued because of its pleasurable effects

Cocaine has served to introduce many addicts to a career of chronic opium addiction Psychopathic cases looking for thrills start with cocaine and increase their dose until the state of anxiety produced by it becomes distressing to them They then begin to use an opiate in order to lessen the disagreeable effects of the cocaine and for a time take both drugs The opiate finally becomes a necessity and cocaine is discontinued for economic reasons Some stop using it because of its obviously bad effects on their health and its tendency to produce emaciation and convulsions

Cocaine is taken by addicts as a snuff or by the hypodermic or intravenous route Snuffing often leads to ulceration or even perforation of the nasal septum

Tolerance to cocaine is built up in human beings but it is never as high as with opiates Animals are said to become more sensitive from continued use of the drug The average cocaine addict will take about 6 grains (0 4 Gm) of the drug per day Psychopathic subjects have been known to take 30 grains (2 0 Gm) per day but few can tolerate such large doses for long periods The simultaneous use of an opiate increases the tolerance to cocaine A cocaine and morphine addict has been known to take 60 grains (4 0 Gm) of cocaine daily along with the morphine *for several days Such large doses* quickly lead to disaster

Symptoms—The effects of small doses of cocaine in the beginning of addiction are pleasant There is a sense of well being exhilaration and optimism Confidence is increased and the libido is enhanced When the accustomed dose is not taken there is a decided let-down with feelings of languor and somnolence Increasing doses and continued use lead to loss of appetite digestive disturbances diarrhea emaciation insomnia peculiar sensations as of crawling under the skin and mild tremors Large doses always cause feelings of nervousness that pass over into anxiety and in addicts who take excessive amounts over long periods the anxiety gradually develops into persecutory delusions and any physical overactivity culminates in convulsions Doses of 20 to 30 grains (1.3 to 2 0 Gm) per day if persisted in will always lead to convulsions and a paranoid type of psychosis Recovery from such psychosis practically always occurs shortly after the drug is discontinued

As with opiates the pleasure derived from the use of cocaine depends on the degree of abnormality of the individual In normal people pleasurable sensations may be absent altogether and even in psychopaths the pleasure is accompanied by disagreeable sensations when large doses are taken The combined use of morphine or heroin with cocaine increases the pleasurable effects of cocaine by adding the element of sedation Some extreme psychopaths who use this combination have at times feelings bordering on ecstasy Deterioration is rapid with such cases Unlike opium cocaine directly increases the propensity of criminally inclined persons to violent crime By its stimulating effect on physical and mental processes the drug increases confidence and daring and makes the users more effective as criminals Paranoid delusions supply some individuals with motives

Morbid Anatomy—Emaciation is usually extreme Scars over the arms shoulders buttocks and legs similar to those found in morphine addicts are often present Some of the scars in the case of cocainism may be due to necrotic action Perforation of the nasal septum is found in some cases There is no other proved morbid anatomy As *with morphinism pathologic changes due to* associated malnutrition and vitamin deficiency may be present

Diagnosis—The history usually establishes the diagnosis Ulcerations of the nasal septum are often present Scars from abscesses and discoloration along the course of veins or fresh needle marks point to addiction but do not differentiate cocaine from opium addiction Laboratory tests are not helpful

Treatment—The drug should be withdrawn abruptly with only symptomatic treatment There are no painful or distressing withdrawal symptoms such as occur in morphinism and collapse never occurs When the drug is withdrawn the body processes that have learned to work normally under the powerful stimulant are depressed

for several days until functional readjustment occurs As a result the patient feels languid but not distressed Where the dose has been large sleep may last as long as thirty six hours In extreme cases it may be desirable to awaken the patient by a small dose of cocaine in order to give nourishment The languor may last for several days longer Appetite rapidly increases and body weight is quickly regained There is a strong desire for the drug for some time, but there is no craving comparable to that following opiate withdrawal The after treatment is similar to that for morphinism Relapses are frequent and are due mostly to personality defects The *prognosis* for combined opiate cocaine addiction is worse than that for single addiction to either drug for the reason that the mixed addict is as a rule more psychopathic

FOOD POISONING

POISONING DUE TO LIVING BACTERIA OR BACTERIAL TOXINS CONTAMINATING FOOD

Definition —Under this heading we shall discuss only that type of poisoning due to the contamination of food with certain bacteria or bacterial toxins Botulism mushroom poisoning mussel poisoning and poisoning due to simple chemicals or allergens in food are discussed separately

The term ptomaine poisoning which is commonly applied by both physicians and laymen to an acute digestive upset of the type described here is misleading and improper because as will soon be shown the trouble is almost always due to living bacteria Actually it is a question whether there is such a substance as a ptomaine, and today no well informed person uses the word. Authorities insist that it should be abandoned, but it is difficult to overcome a habit of speech which has taken such firm hold of laymen newspaper writers, and even the rank and file of the medical profession.

Not only is the term itself inaccurate but worse yet, whenever a series of cases of reported food poisoning is carefully investigated it is found that frequently the diagnosis was wrong and the accused food was not responsible for the illness Thus, in one series of forty three fatal cases in which the reported diagnosis was ptomaine poisoning necropsy revealed in every instance some other cause of death such as appendicitis, ruptured ectopic pregnancy peritonitis tuberculosis meningitis encephalitis acute alcoholism carbon monoxide or metallic poisoning toxemia of pregnancy abortion malaria diphtheria fulminating poliomyelitis bacillary dysentery coronary disease pneumonia or cerebral apoplexy

Food may cause illness either because it contains living bacteria which after ingestion by the victim grow in the bowel or blood and produce toxins or because it contains toxins already formed by bacteria The toxins may be formed and retained in the bacteria, or they may be extruded by these bacteria or, conceivably they may be formed from the food through the action of the bacteria

Etiology —*Both in the* United States and England the commonest cause of poisoning of the type described here is contamination of the food with living bacteria belonging to the Salmonella group The commonest offenders are *Bacillus enteritidis and B aertrycke* Occasionally *B suipestifer* is at fault and occasionally one finds *B paratyphosus* A or B There are good reasons for believing that these strains of *B paratyphosus* commonly come from rodents in which animals they are present in the carrier state They may be innocuous to the host but they are virulent for other susceptible animals and for man Usually they produce an acute enteritis in man and sometimes they even invade the tissues but they seldom produce a typhoid type of long-continued infection with fever Occasionally

they can be grown from the patient s blood and often they produce easily demonstrable agglutinins

Rats and mice are exceedingly subject to epidemics due to bacteria of the Salmonella type and after recovery a considerable number of the animals are left in the carrier state In one census of rats caught in a large city the feces of 4 per cent were found to contain virulent Salmonella Salmonella or Salmonella like organisms have been found also in 24 per cent of swine hence these animals must be looked upon as a reservoir from which food infection can take place Mice in the carrier state are particularly dangerous in bakeries where their droppings can get into the cream fillings for pies choco late éclairs and cakes Because this filling material is often allowed to remain warm in large batches for hours at a time it can serve as an excellent culture medium for toxin producing bacteria

During recent years more and more out breaks of severe poisoning have been traced to infection of food with staphyl ococci and in some streptococci were at fault In a few cases of acute gastro enteritis dysentery bacilli seemed to be the causative organisms

Because there are many cases of apparent food poisoning of the bacillary type in which careful study of the material eaten fails to show any of the usual bacteria so far incriminated Savage has suggested that there probably are other organisms as yet unknown which can produce the syndrome Doubtle s as time goes on and more out breaks are investigated intensively new or ganisms will be found and identified as pos sible causes of this type of trouble

Savage concluded from his studies that most of the strains of bacteria which cause food poisoning are of animal origin and that only a few outbreaks are due to bac teria obtained from human carriers That such human carriers can however infect food and thereby cause outbreaks of gastro enteritis has been proved in a number of instances

There is considerable evidence to indi cate that the egg of the duck can pick up virulent organisms as it passes through the oviduct and in an occasional case of poison ing the trouble has been traced to such eggs

In perhaps the largest number of cases the offending food is chopped meat or sau sage This is due, first, to the butcher s care-lessness in keeping the scraps which he later grinds for too long a time at room tem perature second, to the many opportunities for infection of these scraps as they are being handled or as they lie exposed in a basket and third to the tendency of the Salmonella group of organisms to grow rapidly in meat

In some cases it has been shown that organisms or toxins from the animal s intes tine invaded the meat during life or after death before the abdominal organs were removed This type of contamination is per haps most likely to happen on farms or ranches where an animal may be slaugh tered because it is sick

In most cases food poisoning appears to be due to the presence of enormous num bers of living bacteria in the material eaten This is perhaps particularly true when the food is not well cooked or when in summer it has lain for hours at room temperature In other cases especially when the food has been cooked and particularly in the case of home-canned food the bacteria may have been killed but the heat resistant toxins may have been left Experiments have shown that not only are bacteria of the Salmonella group highly resistant to cooking but the toxins can withstand boiling for a while Fortunately the staphylotoxin which pro-duces such acute poisoning is not only de stroyed by boiling but is either much weak ened or else destroyed by a temperature of from 60° to 65° C maintained for thirty minutes

Filtrates from cultures of Salmonella or ganisms do not produce symptoms when fed to human volunteers or to animals but filtrates of cultures of certain staphylococci recovered from food which has caused poi soning will kill mice and will sometimes produce severe vomiting and diarrhea in human volunteers

Symptoms—In cases of food poisoning of the type here described symptoms generally appear in from two to six hours after the food is eaten Jordan has stated that if the symptoms come in from one to three hours after eating the physician should suspect that the trouble is due to a preformed toxin

produced by a staphylococcus In Salmonella poisoning the symptoms are likely to follow after a somewhat longer interval

The symptoms are usually those of violent diarrhea perhaps with retching prostration, abdominal cramps and dizziness In an epidemic the severity of the symptoms will vary with different individuals In most cases the acute symptoms will be over within from twelve to twenty four hours, leaving for several days some anorexia weakness mild abdominal discomfort or an inability to digest a large meal The staphylotoxin commonly produces nausea vomiting salivation diarrhea chilliness sweating abdominal pain, painful muscle spasm and shock In the severest cases the discharges from the stomach and bowel are bloody Recovery is usually complete in forty eight hours

Diagnosis —The diagnosis of acute food poisoning is often difficult and uncertain unless it is known that the patient is one of a group that fell ill about the same time a few hours after attending a banquet If this fact is established and the symptoms are typical there will usually be little doubt about the diagnosis In order to establish the exact cause a bacteriologist should be called immediately he should obtain samples of the food eaten as well as samples of vomitus feces and blood and later he may study the agglutinating powers of the patient s blood for the suspected bacteria

As stated before in many cases it is not possible to trace the poisoning to any one particular food or to any one organism It is often hard to guess which food was at fault because so commonly foods heavily infected with virulent organisms look good and have no distinguishing taste

Prognosis —Geiger and others who have studied large numbers of outbreaks of food poisoning of the type here described have found that, when the diagnosis is correct and other more serious conditions can be excluded the death rate varies from 0 4 to 1.5 per cent

Treatment —Some physicians begin by giving castor oil but this added purge hardly seems necessary or advisable when the patient has been emptying his bowel violently for a day or two The main indication is to replace lost fluids and salts If vomiting has been continuous for hours Ringer s solution should be given by vein In the severest cases it would be well when laboratory facilities are available to watch the changes that loss of fluids and particularly of gastric hydrochloric acid are bringing about in the carbon dioxide combining power of the blood and in its chloride content When large amounts of gastric juice are lost a harmful alkalosis can develop

Usually all that is necessary is to withhold food until twenty four hours after the cessation of the acute symptoms Plenty of water should be given and after the bowel is well cleared out the patient may have some opium As McRobert pointed out, opiates should not be given too soon because the last thing one wants to do is lock up toxic material or pathogenic bacteria in the bowel

After the vomiting stops, the physician may give tablespoonful doses of colloidal kaolin or bismuth subgallate or subcarbonate These materials tend to adsorb bacteria and toxins and to stop bacterial development through the solidification of the intestinal contents

One of the most important details in the treatment of acute food poisoning is a slow return to a full diet Experiments on dogs have shown that the irritated bowel absorbs poorly and sometimes if the patient goes back too soon to a full diet he will continue to suffer with indigestion for months After a day on water alone he should begin with beef tea or a little gruel Next day perhaps if the bowel has quieted and the attack seems to be well over he may have beef or lamb with rice and toast Contrary to the common assumption milk is not always suitable food for these patients If after a couple of days the digestive tract seems to be ready to take up its work again a smooth diet may be prescribed and this should be followed until all the soreness has gone out of the bowel and the feces are solid again

In some cases the patient must be warned not to take laxatives in order to start the bowel moving again What he calls constipation is really a pause in colonic function which must be expected seeing that the bowel has been emptied so thoroughly One must expect to wait for two or three days before it is full enough to overflow normally again This is particularly true when

the foods first eaten contain little residue from which feces may be made

WALTER C. ALVAREZ

BOTULISM

Definition.—Botulism is a peculiar type of food poisoning produced by the toxins of *Clostridium botulinum* and *Cl. parabotulinum*. It differs greatly from other forms of "food poisoning" in that its symptoms are not so much those of a gastro-enteritis as of an acute encephalitis with paralysis of the ocular and pharyngeal muscles. Another peculiarity is the late onset of the symptoms. Usually they appear from eighteen to thirty-six hours after the ingestion of the toxic food, and sometimes the interval has been as long as three or four days.

Etiology.—The cause of botulism is a large, slightly motile, gram-positive, spore-bearing and largely anaerobic gas-forming bacillus which can be found easily in the soil and sometimes in the straw which is used as packing around the jars which the housewife uses for putting up vegetables and fruits.

There are at least three types of *Clostridium botulinum*, designated A, B and C. Type A usually produces the most concentrated toxin. This is sometimes so powerful that 1 part in 10,000,000 will injure a mouse. The amount of toxin produced depends on the nature of the food, on the pH, on the amount of sugar present, and on other factors modifying the medium.

In the United States the most dangerous toxin producers among the foods have been, in order of frequency, string beans, corn, spinach, olives, asparagus, beets and apricots.

In Europe most of the trouble has been due to toxin formation in sausages and meat and fish pastes; in the United States most of the outbreaks now follow the eating of home-preserved vegetables or fruits served cold as salad. Years ago commercially canned foods were often at fault, but after intensive research K. F. Meyer and his associates showed the packers how they could always be sure of destroying the highly heat-resistant spores that were causing all the trouble. Since then it has been the home-preserved foods that have caused the outbreaks of botulism.

The great difficulty with home canning comes in sterilizing the containers and the food without the use of steam under pressure. Since some of the spores can survive boiling for six hours or subjection to steam under 15 pounds pressure for six minutes, it is easy to see why they sometimes survive the amount of boiling to which they are submitted. Another difficulty arises when the housewife fails to realize that with some packs it takes a long time for enough heat to penetrate into the center of the jar to bring the contents up to the temperature of boiling water.

Morbid Anatomy.—The most significant finding at necropsy is usually congestion and edema of the central nervous system, perhaps with small thromboses and hemorrhages. The meninges are injected, particularly over the base of the brain. Bronchopneumonia is common. All of the abdominal organs are likely to be engorged with blood and the parenchyma of liver and kidneys will be partially degenerated. According to Dickson and Shevky, botulinus toxin impairs the function of nerve endings, particularly in the parasympathetic system. The poisoned nerves can transmit a few strong stimuli, but they soon become fatigued.

Symptoms.—Usually within from eighteen to thirty-six hours after eating spoiled food the patient begins to feel tired and weak. There may be some dizziness and headache, and the bowels usually become obstinately constipated. In only a third of the cases there may be at the beginning signs of irritation of the digestive tract, as nausea, vomiting, diarrhea and abdominal pain.

Then will come disturbances of vision, diplopia, loss of accommodation, mydriasis and drooping of the upper lids. Later there will be great prostration with difficulty in swallowing and speaking, and finally the patient will be unable to swallow without strangling. The saliva becomes thick and ropy and very hard to get out of
There rarely are any sensory
and the mind is usually clear until

The pulse becomes fast and the
ture falls. Most commonly death
through respiratory failure or from
monia. Most of the patients die
to eight days after eating the
If they succeed in living past the
they are likely to recover. Many who

produced by a staphylococcus In Salmonella poisoning the symptoms are likely to follow after a somewhat longer interval

The symptoms are usually those of violent diarrhea perhaps with retching prostration abdominal cramps and dizziness In an epidemic, the severity of the symptoms will vary with different individuals In most cases the acute symptoms will be over within from twelve to twenty four hours leaving for several days some anorexia, weakness, mild abdominal discomfort or an inability to digest a large meal The staphylotoxin commonly produces nausea vomiting salivation diarrhea chilliness sweating abdominal pain, painful muscle spasm, and shock In the severest cases the discharges from the stomach and bowel are bloody Recovery is usually complete in forty eight hours

Diagnosis —The diagnosis of acute food poisoning is often difficult and uncertain unless it is known that the patient is one of a group that fell ill about the same time a few hours after attending a banquet If this fact is established and the symptoms are typical there will usually be little doubt about the diagnosis In order to establish the exact cause a bacteriologist should be called immediately, he should obtain samples of the food eaten, as well as samples of vomitus, feces and blood and later he may study the agglutinating powers of the patient s blood for the suspected bacteria

As stated before, in many cases it is not possible to trace the poisoning to any one particular food or to any one organism It is often hard to guess which food was at fault because so commonly foods heavily infected with virulent organisms look good and have no distinguishing taste

Prognosis —Geiger and others who have studied large numbers of outbreaks of food poisoning of the type here described have found that, when the diagnosis is correct and other more serious conditions can be excluded the death rate varies from 0 4 to 1.5 per cent

Treatment —Some physicians begin by giving castor oil but this added purge hardly seems necessary or advisable when the patient has been emptying his bowel violently for a day or two The main indication is to replace lost fluids and salts If vomiting has been continuous for hours Ringer s solution should be given by vein In the severest cases it would be well when laboratory facilities are available to watch the changes that loss of fluids and particularly of gastric hydrochloric acid are bringing about in the carbon dioxide combining power of the blood and in its chloride content When large amounts of gastric juice are lost a harmful alkalosis can develop

Usually all that is necessary is to withhold food until twenty four hours after the cessation of the acute symptoms Plenty of water should be given and after the bowel is well cleared out the patient may have some opium As McRobert pointed out, opiates should not be given too soon, because the last thing one wants to do is lock up toxic material or pathogenic bacteria in the bowel

After the vomiting stops the physician may give tablespoonful doses of colloidal kaolin or bismuth subgallate or subcarbonate These materials tend to adsorb bacteria and toxins and to stop bacterial development through the solidification of the intestinal contents

One of the most important details in the treatment of acute food poisoning is a slow return to a full diet Experiments on dogs have shown that the irritated bowel absorbs poorly and sometimes if the patient goes back too soon to a full diet he will continue to suffer with indigestion for months After a day on water alone he should begin with beef tea or a little gruel Next day perhaps if the bowel has quieted and the attack seems to be well over, he may have beef or lamb with rice and toast Contrary to the common assumption milk is not always suitable food for these patients If after a couple of days the digestive tract seems to be ready to take up its work again a smooth diet may be prescribed and this should be followed until all the soreness has gone out of the bowel and the feces are solid again

In some cases the patient must be warned not to take laxatives in order to start the bowel moving again What he calls 'constipation is really a pause in colonic function which must be expected seeing that the bowel has been emptied so thoroughly One must expect to wait for two or three days before it is full enough to overflow normally again This is particularly true when

OTHER TYPES OF INJURY DUE TO FOOD

So long as certain bacteria and cocci do not enter into the process the putrefaction of meat or fish or casein does not seem to produce any substance which the digestive tract cannot handle with ease Lumholtz the explorer described Australian savages gorging themselves on the meat of a stranded whale which was so high that it could be smelled for miles inland and Stefansson has told of Eskimos eating with impunity fish which had been piled up and allowed to rot for months until it resembled Limburger cheese

Impure milk and ice cream made from it are common sources of gastro enteritis especially in the hot summer months The principal sufferers are infants and children Again the trouble is due to contamination by bacteria derived from an infected udder or from manure dirty cans flies or the unclean hands of human carriers At times cheese becomes toxic when the producer fails to exclude certain bacteria from his vats The outstanding symptom following the eating of such cheese may be a severe headache

Many allergic persons are more or less violently poisoned by certain foods but this topic will not be taken up here because in these cases it is not the food but the consumer who is at fault

There are a number of edible plants which are somewhat poisonous and some like manioc and *sweet potatoes* which are poisonous in the raw state can be prepared in such a way as to be harmless *Sprouting potatoes* eaten raw are particularly dangerous The symptoms are vomiting diarrhea colicky pains headache prostration constriction in the throat stiffness of the tongue marked mydriasis or miosis disturbances in vision and hallucinations Certain types of vetches such as *Lathyrus sativa* and the *Cicer* or chick pea can produce poisoning in countries in which large amounts of this food are eaten The main symptom is stiffness in the legs

In some parts of the world such as Japan and Hawaii certain fishes must not be eaten because they are poisonous and at certain unpredictable times of the year mussels are exceedingly so Recently it has been learned that this is due to the presence of myriads of little dinoflagellates The first symptom of poisoning which comes soon after the food is eaten is a feeling of numbness and prickling about the mouth This should be the signal for a prompt emptying of the stomach

Ergotism is due to the long continued eating of rye which has been infected with the fungus *Claviceps purpurea* The symptoms are those of injury to blood vessels

As is well known the eating of certain types of mushrooms, particularly the *Amanita phalloides A muscaria* and *A verna* leads to severe poisoning not only by muscarine but by several other toxic substances. Perhaps because the toxins are different there are two main types of mushroom poisoning In one—the more hopeful so far as treatment is concerned—the symptoms are largely those of gastro enteritis with diarrhea vomiting abdominal colic great thirst and collapse In the second and more fatal type the symptoms are largely those of injury to the nervous system with headache, somnolence trismus mydriasis sometimes opisthotonos with other forms of muscular crampings perhaps blindness loud cries and finally coma

The symptoms commonly appear in from four to five hours after the meal Atropine is the antidote for muscarine and should be given in large doses The stomach should be emptied and when there is much destruction of the blood transfusions should be given Solutions of dextrose may be administered intravenously to help protect the badly injured liver According to Limousin and Petit (1932) the fresh chopped brains and stomachs of several rabbits given by mouth will combine with the toxin and act as a specific

Fruits, and particularly apples when heavily indulged in can be dangerous if they have been sprayed with salts of lead and arsenic used to eradicate insect pests For some time the United States Government has been taking measures to obviate this danger Many persons fear that they will be poisoned if they eat food cooked in aluminum pots but there is no foundation for this phobia Aluminum hydroxide is now given in large doses to patients with peptic ulcer and they are not poisoned

WALTER C ALVAREZ

survive the intoxication succumb to an inhalation pneumonia which arises from their inability to swallow properly During the illness the digestive tract often seems to be paralyzed and food remains for a long time in the stomach

Diagnosis —This may be easy when a number of persons who ate at the same table fall ill about the same time with the typical ocular palsies or when the patient remembers having eaten food which looked spoiled and tasted peculiarly or when on a farm chickens given spoiled food are dying with ' limberneck When only one person is ill the problem of diagnosis is more difficult and the physician may think of encephalitis or poliomyelitis or of the various other causes of bulbar paralysis or ophthalmoplegia If any of the suspected food can be secured an expert can soon tell whether or not it contains the toxin of *Clostridium botulinum* If it does a small portion injected into a mouse will soon cause paralysis and death

Prognosis —The prognosis is bad In the United States two thirds of the victims die In Germany the disease is often milder and the mortality lower

Prevention —The prevention of botulism depends largely on the success of campaigns to educate housewives not to take chances with food from home packed jars especially when spoilage has taken place as shown by leakage over the rubber ring

At times, the infected food will look spoiled it may be softer than it should be it may contain gas bubbles or it may have a cheesy or rancid smell On the other hand infected food may look all right and it may fail to give off a peculiar odor even when it is warmed

In some cases the toxin has been so concentrated that simple tasting of the food by the cook has led to her serious illness Home preserved food which has bubbled over or has shown any other signs of spoilage should not even be tasted Nor should it be thrown out in the barnyard because this leads commonly to the death of chickens and other domestic animals

As one cannot always detect signs of spoilage the only safety lies in boiling all home-preserved foods for at least six minutes before they are served to destroy any toxin that may be present Because this amount of boiling will not destroy spores and because it is still a question whether or not they can grow in the body and there produce dangerous amounts of toxin it is not *advisable to boil and eat definitely spoiled food* The worst thing the housewife can do is to cover up the taste of slightly spoiled food with some form of dressing and then serve it unheated as a salad To do this is to invite disaster which may wipe out the whole family

Treatment —The best treatment of course is prevention Once the typical symptoms have appeared the patient is likely to go downhill in spite of any therapy If the antiserum can be obtained quickly it should be used because evidence is accumulating that it sometimes saves life Naturally there is much more chance of its doing good when it is given before paralysis appears Unless the type of the infecting organism is known a polyvalent serum will have to be used After first testing the patient for sensitiveness to horse serum one large dose of from 5000 to 10 000 units should be given intravenously

Every effort should be made to protect the patient from fatigue and a little morphine may have to be used to lessen suffering If the patient is seen early, it may help to wash out his stomach since this organ tends to retain the offending food for several days Care must be taken however lest the procedure induce dangerous fatigue and strangling Any feeding that is attempted should perhaps be done with the help of a fine Levin tube through the nose Food given by mouth is likely to produce strangling and pneumonia Perhaps the sticky ropy mucus that is so troublesome can be wiped or sucked out of the throat Small doses of ipecac or emetin will sometimes loosen it and thus bring great relief

It is possible that more patients would be saved from a respiratory death if they were placed in a respirator The danger from pneumonia can be lessened by the use of the oxygen tent or B L-B mask as soon as the first signs of cyanosis appear Because the muscles can so easily become paralyzed with effort every precaution should be taken to spare the patient exertion

WALTER C ALVAREZ

saved the site of the bite shows a ragged and indented scar from destruction of tissue

On the other hand after the bite of the cobra there is slow and moderate swelling and little or no discoloration The first major symptom is difficulty in breathing and this is steadily progressive If recovery takes place it is rapid with but little destruction of tissue at the wound

Between these extremes are various ratios of the toxic elements producing a variety of symptoms Some of the African vipers produce a combination of tissue destruction and neurotoxic reaction The North American rattlesnakes the copperhead and the moccasin produce largely hemolytic reaction but their predominating hematoxin is not of such sinister or rapid effect as that of the Central and South American vipers Then again the relative toxicity varies among them Drop for drop the venom of the copperhead is not so powerful as that of the rattlesnake and while the poison of the water moccasin is slower in effect than that of a rattlesnake and more quickly neutralized with *antitoxin its necrotizing effect if* unrestrained is ultimately more pronounced The small and gaudily colored coral snake of our southern states with a number of allies in the tropics is a degenerate New World ally of the cobra It secretes a powerful neurotoxin

For the injection of venom the serpent is provided with a pair of highly specialized teeth in the anterior portion of the upper jaw With the viperine types these teeth are quite the duplicate of the hypodermic needle having an orifice at the tip whence the poison is discharged Each fang or hollow tooth connects with a venom gland situated in the temporal region of the head With the viper the fangs are of such excessive length that they are necessarily folded back against the roof of the mouth when the jaws are closed They are attached to movable bones With the cobras and their allies the fangs are short but stout and permanently erect

Against this race of formidable creatures man has been studying and battling for years for a remedy The high human mortality in India amounting to more than 20 000 lives a year inspired Albert Calmette of the Pasteur Institute to experiment with antivenom sera more than thirty years ago A noted expert on the poisons of reptiles and insects he recognized the varying types of poisons in different snakes His early experiments were with a polyvalent serum produced by immunization of horses with repeated and stepped up injections of a mixture of cobra and viper venoms Later on, he found that specific immunization with the poison of one particular type of snake was far more efficacious This is now the general practice in the production of all antivenom sera The usual time necessary to produce immunity in a horse is now six to eight months After this period the animal develops remarkable resistance readily enduring many times the lethal dose of venom The neutralizing effect of such sera has been greatly strengthened during the past ten years by filtration processes which produce high concentration

A fine institute for the study of snake venoms has been developed at Sao Paulo Brazil under the auspices of that government As an example of the economic value *of this work it should be noted that thirty* years ago Brazil recorded several thousand deaths a year from the bites of snakes Careful tabulation recorded less than 50 deaths during 1929 Several types of serum are widely distributed One is for the bushmaster or surucucu another for the fer-de-lance (jararaca) and allied species another for the rattlesnake and a distinct serum for the coral snakes

A careful tabulation carried over several years indicates an annual mortality of about 100 lives in the United States Several hundred cases of snake bite occur each year but in many instances recovery takes place The Antivenin Institute of America at Glenolden Pennsylvania has a scientific consulting board and a series of subsidiary stations in various parts of the country each in charge of an accredited expert This institute produces a polyvalent serum for the bites of the rattlesnake moccasin and copperhead The venoms of these three types largely of a hematoxic nature are similar enough to render a single grade of serum entirely practical and efficacious

Treatment —The writer has been surprised to note the general lack of understanding of the treatment of snake bite in

SNAKE VENOM POISONING

The actual composition of snake venom is not altogether clear One of the best definitions is that of Dr Adolph Monaelesser which may be briefly stated as follows Snake venom is composed of a mixture in variable proportions of protein substance mucus and debris of epithelial cells some fatty matter, and salts such as calcium chloride and phosphate also ammonia and magnesia The density is somewhat greater than that of water, varying in specific gravity from 1 030 to 1 050 The proteins contain the various active toxins which by certain methods can be removed or some of them inactivated as has been demonstrated by researches in the New York Zoological Park'

The fresh venom of different snakes varies in color from deep amber to yellowish green straw color or almost colorless and is in gross appearance a viscid fluid The dried venom is quickly soluble in distilled water It retains its full toxicity for years if kept in darkness but slowly deteriorates if exposed to light Owing to its contamination with bacteria from the reptile s mouth it quickly decomposes if left in a fluid state

Grossly speaking the venoms of all serpents are composed of two primary elements a hematoxin and a neurotoxin The former creates great destruction of the red blood cells and tissue It causes extensive swelling discoloration by extravasation and certain other manifestations The other primary element neurotoxin produces little swelling but its action is quite as formidable as the action of hematoxin It attacks the nerve centers particularly the sympathetic system, also the phrenic nerve The thoracic muscles become paralyzed to such an extent that the victim may succumb through inability to breathe

The major differences in snake venoms are due to varying proportions in the hematoxic or neurotoxic elements These elements also differ in their relative toxicity among various species of serpents Analyses indicate that each of the elements is complex in composition and that these components when separated may produce certain local manifestations distinctly recognizable from the broader symptoms of the combined element

As examples of the varying proportion of the hematoxic and neurotoxic elements we may take the prevailing viper of the American tropics and the Indian cobra They represent the two extremes The viper is known under various names In Central America it is called the *barba amarilla* and in Martinique and St Lucia the only islands in the West Indies where it occurs it is commonly termed the *fer de lance* In northern South America it is usually referred to as the *mapepire balsayn* and in southern Brazil as the *jararaca* The symptoms following its bite are rapid and extremely dramatic Immediate swelling and discoloration take place There is an oozing of blood from the mouth the conjunctiva and even from the stomach during the reflex vomiting which frequently occurs with the greater number of snake bites There are bloodlike ejections from the bladder The victim sinks into a condition of coma and death may result in six to twelve hours These symptoms point to a poison with extremely potent hemolytic action The blood stream is so thinned and the walls of the vessels so broken down that there is a tremendous leakage over great areas If the injection of a neutralizing serum is delayed in such cases a blood transfusion is usually necessary to save the patient If the patient is

DEFICIENCY DISEASES

INTRODUCTION

The nutritional deficiencies are a group of diseases caused by an inadequate intake or absorption of essential food factors The inadequacy may be on the basis of usual or normal requirements or may be a relative inadequacy a failure to meet abnormally increased needs Though often thought of as referring only to vitamins the essential food factors include the energy principle (calories) protein and certain amino acids some minerals and perhaps fatty acids as well In medical practice deficiencies of single factors alone are rarely encountered nearly always they are multiple although usually the signs and symptoms of one or two predominate Curiously complete starvation is not accompanied by evidence of deficiencies other than calories

Although the effects of many of the deficiencies are represented by well known syndromes such as pellagra and scurvy and the symptoms of a deficiency of such factors as salt have long been clearly recognized as deficiency states the modern concept of deficiency disease really begins with the discovery of the vitamins These substances were hinted at by Lind s classical observations on lime juices and scurvy but had their real beginning in the search for the substance in rice bran that cured polyneuritis in pigeons an unknown substance to which Funk gave the name vitamine From these studies came the impetus for the discovery of not only thiamine (Vitamin B_1) but nearly a dozen other vitamins and a new concept which has brought together old and new syndromes in a group of diseases with well-defined characteristics Furthermore study of these substances their functions and the effects of a deficiency in them has greatly increased our knowledge of physiology as well as our clinical knowledge of disease

In the beginning medical interest and knowledge were confined to the gross manifestations of severe deficiencies These disclosed themselves as well known classical diseases whose etiology and pathogenesis had long been obscure—scurvy beriberi pellagra hunger edema keratomalacia and others As further progress was made new essential nutritive elements and the syndromes due to their deficiency were discovered—vitamin K and the hemorrhagic states related to it for example New and hitherto unrecognized results of the deficiencies of previously known factors were found Finally it has become known that besides the severe and advanced deficiencies hitherto recognized there are many instances of deficiencies so slight that either they cause no recognizable symptoms or they produce symptoms too mild and nonspecific to constitute reliable diagnostic evidence of the deficiency To detect such deficiencies objective laboratory tests and special procedures are required and as the need for these arises they are rapidly being developed

The various nutritive factors and the diseases associated with them have many characteristics which serve to distinguish them as a group Except for the energy principle and protein the various substances are needed in very small amounts much as catalysts or enzymes This is true even of certain minerals the nutritive requirements of which are many times smaller than the pharmacologic doses Even for protein the required amounts of the *essential* amino acids are relatively very small

None of the essential factors can be formed or synthesized by the body they must be obtained in a preformed state in the diet This characteristic which is relative and shows considerable species variation is well expressed in man He can complete the synthesis of vitamin A from carotene can obtain vitamin K from the action of bacteria in his intestine and can form vitamin D from the action of ultraviolet light on his integument Except for these limited abilities he is dependent on preformed substances from outside sources

Another characteristic of the various nutritive factors is their relative lack of toxic-

various parts of this country Unfortunately, cauterization is frequently employed, but a lethal fluid has been hypodermically injected and the first thought should be to prevent its absorption by ligation this to be immediately followed by drainage Ligation and incision should be the first steps after snake bite

We are constantly learning more about the action of snake poison Dudley Jackson of San Antonio Texas has recently demonstrated that a considerable portion of the injected venom lingers in the bitten area for some time This indicates the necessity for *incision* to invade the fang punctures and the desirability of immediate *forced suction* from the area of the wounds Suction devices similar to breast pumps have been found highly efficient and serous accumulation thus removed several hours after from the area of a severe bite has been found to contain heavy traces of venom There is a rapid and notable accumulation of serum in the bitten area This is usually discharged in profuse quantities from the drainage incisions which should be covered with dressings kept wet with some mild antiseptic

Antivenom serum is most efficacious when injected immediately after a bite but it should be administered even if the victim has already approached a condition of collapse *In delayed cases however the serum* is usually injected too late to be properly taken up by the circulation and thus neutralize the venom injected at the time of the bite

The bite of a copperhead or small rattle snake is not ordinarily fatal although it may be very serious Serum may be injected as late as a day or even two days after the symptoms of swelling have developed It is far better however, to inject it as soon as possible in order to quickly neutralize the poison and thus prevent destruction of the blood corpuscles A large rattlesnake may inject enough poison to produce death in ten to twelve hours or in a much shorter time if as occasionally happens a vein is punctured Ordinarily serum is injected subcutaneously in the abdominal region or between the shoulder blades If extremely rapid and alarming symptoms develop the safest course is to administer the serum intravenously

The blood stream has the property of neutralizing a certain amount of poison Consequently, in a large-bodied adult with full blood content, not so much serum may be necessary as with a small and slight person *Thus it should be understood that considerably more of the neutralizing antivenin* is necessary with a child and while 20 cc of serum may be found all that is necessary to produce a rapid alleviation of symptoms with a large adult, at least 30 cc or more may be necessary with a very young person The first injection should be 10 cc to be repeated at intervals, until there is a definite and favorable reaction

Both ligation of the wounded area with frequent slacking and repeated suction should be employed It may be necessary to continue this treatment for several hours after the bite and if the swelling is extremely extensive small cruciform incisions over the swollen area are indicated Such incisions kept moist will allow profuse serous drainage

The local use of *permanganate of potassium* except in very mild solution will result in destruction of tissue Used in extremely dilute solution (1 2000) in the immediate wound areas permanganate may *oxidize a certain amount of the venom* but it does little good owing to its lack of penetration However it has germicidal properties It is utterly rash to rub pure crystals of permanganate into the wounds Nothing could be more foreign to the treatment of snake bite than such practice

As not only the immediate area of the wound but a considerable portion of the neighboring tissue is much damaged and therefore, subject to secondary *bacterial invasion* and as the bite itself sometimes is attended by specific infection from microorganisms in the snake s mouth, the wounds should be kept covered with a wet and mildly antiseptic dressing for several days or until a time when all symptoms of swelling are gone Such wounds are usually stubborn and may remain open for several weeks

RAYMOND L DITMARS

DEFICIENCY DISEASES

INTRODUCTION

The nutritional deficiencies are a group of diseases caused by an inadequate intake or absorption of essential food factors The inadequacy may be on the basis of usual or normal requirements or may be a relative inadequacy a failure to meet abnormally increased needs Though often thought of as referring only to vitamins the essential food factors include the energy principle (calories) protein and certain amino acids some minerals and perhaps fatty acids as well In medical practice deficiencies of single factors alone are rarely encountered nearly always they are multiple although usually the signs and symptoms of one or two predominate Curiously complete starvation is not accompanied by evidence of deficiencies other than calories

Although the effects of many of the deficiencies are represented by well known syndromes such as pellagra and scurvy and the symptoms of a deficiency of such factors as salt have long been clearly recognized as deficiency states the modern concept of deficiency disease really begins with the discovery of the vitamins These substances were hinted at by Lind s classical observations on lime juices and scurvy but had their real beginning in the search for the substance in rice bran that cured polyneuritis in pigeons an unknown substance to which Funk gave the name vitamine From these studies came the impetus for the discovery of not only thiamine (Vitamin B_1) but nearly a dozen other vitamins and a new concept which has brought together old and new syndromes in a group of diseases with well defined characteristics Furthermore study of these substances their functions and the effects of a deficiency in them has greatly increased our knowledge of physiology as well as our clinical knowledge of disease

In the beginning medical interest and knowledge were confined to the gross manifestations of severe deficiencies These disclosed themselves as well known classical diseases whose etiology and pathogenesis had long been obscure—scurvy, beriberi pellagra hunger edema, keratomalacia and others As further progress was made, new essential nutritive elements and the syndromes due to their deficiency were discovered—vitamin K and the hemorrhagic states related to it for example New and hitherto unrecognized results of the deficiencies of previously known factors were found Finally it has become known that besides the severe and advanced deficiencies hitherto recognized there are many instances of deficiencies so slight that either they cause no recognizable symptoms or they produce symptoms too mild and nonspecific to constitute reliable diagnostic evidence of the deficiency To detect such deficiencies objective laboratory tests and special procedures are required and as the need for these arises they are rapidly being developed

The various nutritive factors and the diseases associated with them have many characteristics which serve to distinguish them as a group Except for the energy principle and protein the various substances are needed in very small amounts much as catalysts or enzymes This is true even of certain minerals the nutritive requirements of which are many times smaller than the pharmacologic doses Even for protein the required amounts of the *essential* amino acids are relatively very small

None of the essential factors can be formed or synthesized by the body they must be obtained in a preformed state in the diet This characteristic which is relative and shows considerable species variation is well expressed in man He can complete the synthesis of vitamin A from carotene can obtain vitamin K from the action of bacteria in his intestine and can form vitamin D from the action of ultraviolet light on his integument Except for these limited abilities he is dependent on preformed substances from outside sources

Another characteristic of the various nutritive factors is their relative lack of toxic

ity or potentiality for harm Excessive amounts are in general excreted without untoward effect, even of such minerals as iodine, if the amounts are at all near the range of nutritional requirements This lack of untoward effect, however is concerned with a direct toxic action and not with possible ill effects of a nutritional nature caused by an imbalance of nutritive factors Little is known of possible disturbances of this kind, but there is sufficient evidence to indicate that such disturbances can occur A simple example is the increased requirement for thiamine caused by an increased carbohydrate (calory) intake

All of the known essential nutritive products are distinct chemical substances The nature chemical composition and structure of *most of them are known Many of the* organic substances have been isolated and synthesized—one of the most brilliant achievements of modern chemistry In a number of instances the specific factors are members of a related group of chemical substances natural and artificial some of which may possess an effect similar to that of the specific nutritive factor Usually such related substances have a less marked effect than that of the specific factor occasionally (vitamin K) the action of a related even an artificial compound is greater than that of the natural essential substance

Because these nutritive essentials are known chemical substances we have considerable knowledge of their physical characteristics and reactions Much is known of even the biochemical behavior of many of them For example many members of the so called B complex of vitamins are concerned in oxidation reduction reactions involving the transfer of oxygen and hydrogen in the intimate biologic processes of metabolism Thiamine is known to play an important and necessary role in the end stages of the oxidation of glucose Yet the relation of such functions and reactions to disturbed physiology the mechanism by which even known alterations in physiology produce clinical signs and symptoms characteristic of the specific deficiencies remain unknown in most cases Recently more subtle functions and reactions such as those concerned with detoxification mechanisms immune body production and the like disclose new fields of study and development and suggest nutritional disease of a kind not manifested in the usual recognized manner but as a disturbance in metabolic processes concerned with exogenous and endogenous toxins and in the response to other disease. It is apparent that such actual nutritional deficiencies as occur under these circumstances will be of the so called conditioned type

As a group the nutritional deficiencies that is the diseases resulting from a lack of the specific nutrients have many characteristics in common as do the nutritive factors themselves Clinically these deficiency diseases appear in epidemic as well as in endemic and sporadic form The sporadic cases are of more immediate interest to *practicing physicians but existing endemic* deficiencies provide a large backlog of nutritional disease which constitutes a threat of complication in all manner of other disease and under conditions of stress often develops into a major problem by *itself*

Clinically a distinction is also made between those uncomplicated deficiencies which develop independently as the result of a failure of the nutritive supply and those which are brought about by the influence of some other disease on the intake or absorption or utilization of food The latter are known as conditioned deficiencies They constitute the largest group of deficiencies seen in medical practice and because of the fundamental nature of nutrition are found in all specialties and types of practice More and more the conviction is growing that most of the recognizable deficiencies even of the milder grades are the result of some individual circumstance or condition which precipitated or conditioned a deficiency More and more it is being recognized that many of these relationships are of a subtle kind concerned with infection with metabolic disorders with chemotherapy and hence less nutritional than metabolic In this direction lies much of the future development in the field of nutrition In many instances however the development of these conditioned deficiencies is made possible by the existence of a mild endemic type of primary nutritional deficiency common to many of the population

So far the goal of clinical medicine *in the*

prevention and control of nutritional de ficiencies has been the absence of disease , little has been done in the direction of positive health Little is known of optimum nutrition or even of optimum amounts of single factors The problem is exceedingly complex concerned as it is with the inter action of a large number of independent major nutritive factors besides many lesser influences Yet in the direction of such optimum nutrition lies a potentially tremen dous advance in public and individual health

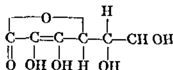
SCURVY

Definition—Scurvy is a nutritional dis order caused by prolonged inadequacy of the diet in vitamin C (ascorbic acid) In its mild forms it gives rise to apathy anorexia fatigability and loss of strength with ten derness of the extremities or even of the whole body, to these symptoms is added in more severe cases a striking tendency to hemorrhage The manifestations of the dis ease depend to some extent on the age of the patient Infantile scurvy (Barlow s dis ease or Moeller Barlow disease) differs from adult scurvy principally in the extent to which the growing bones are involved but discrepancies in morphology and symptoma tology based on the patient s age level do not justify separation of the resulting syn dromes into two entities for they are of one etiology

History—The name scurvy appeared first in the Middle Ages as a folk word having various forms phonetically allied in several European tongues Its ori gin is therefore obscure The Latinized "scorbutus" is an artifi ial implant



Whether scurvy was observed by Hippocrates is a matter of dispute Possibly the earliest clear-cut descrip tion of the di ease was made by de Joinville whose ac count of its appearance among the Crusaders of the thirteenth century leaves no room for doubting its iden tity Its ravages in mar time voyages during the Age of Discovery were appalling Scurvy cost Vasco da Gama 100 lives among his crew of 160 men in his voyage around the Cape of Good Hope in 1497 and disabled all but 10 of Jacques Cartier s crew of 110 men on their expedition to Newfoundland in 1 35 To Joseph Lind an officer of the British navy belongs the credit of amassing convincing evidence first, that scurvy is a disorder of nutrition and not a contagion or strictly an occupational disease and second that it results not from excessive consumption of certain articles of diet but from insufficient intake of others His 'Treatise on the Scurvy" published in 1753 was ultimately respon sible for the introduction of lemon juice into the sea man s ration Sharp as was the decline in the general morbidity of scurvy after the widespread adoption of effective preventive measures the disease has neverthe less continued to appear in circumstances of stress For years the incidence of scurvy in Ireland bore a recipro cal relation to the success of the potato crop In the siege of Paris in 1870 and 1871 the disease ravaged both the military and the civil population it appeared among the troops of both contestants on various fronts of the World War of 1914–1918 especially in Russia, Rumania and Mesopotamia, and among the people of Austria during the postwar economic depression

Infantile scurvy has a somewhat different story Glisson whose treatise on rickets was published in 1650 had seen scurvy in London children and had ascribed it to defective environment In 1859 and again in 1862 Moeller of Konigsberg reported cases of what he called "acute rickets the descriptions of which are clearly those of scurvy· this erroneous interpretation of nosologic evidence spread a cloud of confusion over virtually the entire Germanic school of medical thought. Barlow of London in 1883 published indubitable ana tomic evidence that scurvy may affect infants His view was accepted as authoritative throughout a large por tion of the Western World although most Germans continued for decades to regard the identity of "die Moeller Barlowsche Krankheit" and infantile scurvy as open to question Modern chemical studies have dis pelled all doubt.

Scurvy was produced in laboratory animals by Theobald Smith in 1895 but the discovery was not followed up The experimental period began actually with the work of Holst and Frolich which was pub lished in 1907

In 19 8 Szent Gyorgyi isolated from the suprarenal glands of oxen and from various plant sources a crystal line compound of formula $C_6H_8O_6$ which he named hexuronic acid The wide distribution of this com pound in animal tissues and in growing plants was soon appreciated as were also its strong reducing properties but it was not until 1932 that Szent-Gyorgyi determined by appropriate feeding experiments that he had been dealing with the specific antiscorbutic factor vitamin C Simultaneously and independently King and Waugh isolated a highly active antiscorbutic compound from lemon juice and showed that it was identical with "hex uronic acid By common agreement the latter term was abandoned in favor of ascorbic acid by which the pure vitamin is now universally designated The American Medical As ociation for a time advocated the name cevitamic acid

Etiology Chemistry of the Vitamin.—The structural formula of the vitamin is

This is the *l* form the *d* form has no anti scorbutic activity It is readily soluble in water methyl alcohol, ethyl alcohol and acetone, and is precipitated by lead In watery solution in the presence of traces of heavy metals (*e g* copper) acting as catalysts it takes up atmospheric oxygen rapidly with resulting loss of antiscorbutic activity The rate of oxidation is accelerated by heat light and by alkalinity of the medium The assay of biologic fluids for ascorbic acid content depends on quantitative reduction of reagents under specific control of the medium in which the reaction takes place Methods now in common use employ either 2 6 dichlorophenol indophenol or methylene blue as both oxidizing agent and redox indicator

The part played by vitamin C in physico chemical mechanisms *in vivo* is still obscure It is thought to be involved in physiologic oxidations in addition it is known to be essential for the proper formation of collagen by fibroblasts, and there is indirect evidence that it participates in the production of intercellular material in other tissues but the details of these reactions have not been elucidated In premature infants the administration of ascorbic acid suppresses the urinary excretion of hydroxyphenyl lactic and hydroxyphenyl pyruvic acids

The juice of ripe oranges has a fairly constant content of vitamin C at about 0 5 mg per cubic centimeter Other citrous fruits though showing greater variation under market conditions contain similar quantities In general there is a fairly close parallelism between the ascorbic acid content of plant tissues and their store of carotenoids or chlorophyl, green leaves and shoots of all kinds as well as tubers whether edible or those generally regarded as inedible are sources of vitamin C

In animal tissues the concentration of ascorbic acid is highest in the adrenal hypophysis corpus luteum lens and aqueous humor and somewhat less high in brain pancreas liver spleen and kidney it is considerably lower in muscle tissue distinctly low (about 0.5–1 5 mg per cent) in blood plasma and virtually absent from fat Human milk normally contains from 4 to 7 mg per cent of ascorbic acid, depending partly on individual performance partly on fluctuations in the vitamin C content of the mother s diet Cow's milk while it has only one third or one quarter as much vitamin maintains a constant level at all seasons since the concentration is independent of the vitamin C content of the fodder Chemical synthesis of ascorbic acid now competes successfully with its isolation from natural sources

The human organism is unable to synthesize ascorbic acid and it is this dependence on intake which determines susceptibility to scurvy From a number of sources evidence has been adduced to indicate that the daily metabolic requirement in man—the quantity of ascorbic acid normally utilized in the body—is about 1 mg per kilogram of body weight When the dietary supply exceeds this amount, retention occurs until the stores are filled after which loss through urinary excretion takes place above a threshold level of approximately 1 5 mg per 100 cc of plasma On an average diet the normal adult excretes from 5 to 50 mg of ascorbic acid in the urine in twenty four hours An increase in the intake augments this output though not immediately and not quantitatively If to an average diet one adds a daily supplement of 500 mg of ascorbic acid equivalent to about 1 liter of orange juice the urinary excretion of the vitamin will rise significantly within the first or second twenty four hour period and will level off at about 80 per cent of the intake After this equilibrium has been established withdrawal of the supplement results in a similarly steep falling off of the excretion, so that within three or four days the output has returned to the starting level It would seem in other words, that the organism has a limited capacity for storing vitamin C that on an average diet the stores are not filled to the saturation point, and that after saturation the major portion of the intake spills over into the urine The fate of the unaccounted fraction of the supplement is unknown at the present time evidently it is not destroyed in the alimentary tract nor excreted in the stools for intravenous injection of the supplement gives virtually identical results the supplement appearing in the urine more promptly but only slightly more completely Infections and hyperthyroidism accelerate vitamin depletion Withdrawal of vitamin C from the

diet of a normal subject for a period of one or two weeks causes a clearly detectable change in the economy of the vitamin when a supplement is subsequently added the daily administration of a liberal quantity of ascorbic acid following such a vitamin free period may fail to produce an increased output in the urine for four days or even longer

In cases of manifest scurvy the body stores of ascorbic acid are significantly depleted the plasma concentration is zero or nearly so and the small quantities reported present in urine may well reflect merely the error of analysis In the depletion process the white blood cells and platelets which normally contain ascorbic acid at a concentration some thirty times as great as that of cell free plasma retain their stores with relative avidity yet they likewise lose their titrable ascorbic acid by the time scorbutic symptoms appear On therapeutic administration of the vitamin relief of symptoms and signs of scurvy precedes the restoration of a normal urinary output of ascorbic acid or the establishment of a stable plasma concentration at a normal level

The time required to bring out symptoms of scurvy on a deficient diet varies greatly in ordinary clinical circumstances partly because complete deprivation is seldom encountered except under experimental conditions partly too because of the delaying effect of even a small intake of the vitamin In a notable human experiment carried out by Crandon under controlled conditions of strict dietary deficiency the subject s plasma level of ascorbic acid fell to zero by the forty first day the white blood cells and platelets became depleted after four months yet objective signs of scurvy in the form of cutaneous hemorrhages were not evident until the 161st day of the experimental diet These intervals presumably represent approximately minimal values Subjective symptoms of a less specific nature—languor fatigability and anorexia—evidently preceded the appearance of objective signs of scurvy but their import became clear only in retrospect when the resumption of an ample vitamin intake promptly dispelled them Most cases of scurvy seen in infancy develop six months or so after the institution of artificial feeding A few examples have been reported in infants considerably younger but in these instances the mother could invariably be shown to have subsisted on an inadequate diet during pregnancy, and the period of vitamin C deprivation so far as the infant was concerned obviously commenced before birth Many examples are on record of scurvy breaking out in a ship s crew within a few weeks of sailing but here one is inclined to incriminate the on shore diet and to suspect that the subject was in a state of relative deficiency at the time of embarkation It is quite evident that between the state of replete stores and that of active scurvy there is a broad zone in which a subject may be symptom free and yet subsist on a demonstrably low turnover of ascorbic acid

Pathology—In fatal cases of scurvy in adults hemorrhages into the skin are found as a rule in only one of the twenty three cases reported by Aschoff and Koch were superficial hemorrhages absent They may vary from the smallest petechiae to large ecchymoses The larger spots are apt to be found on the trunk the smaller ones on the extremities Almost invariably the lower extremities are more markedly involved than the upper the face palms soles lateral aspects of the thigh and region of the knee joint tend to be spared Many of the hemorrhages involve hair follicles or at least begin there keratosis pilaris frequently occurs in association with the disease

Edema and accumulation of fluid in body cavities are characteristic of scurvy the transudates remaining strikingly uncontaminated with blood Localized areas of superficial edema are apt to overlie deep hemorrhages which occur most frequently in the lower extremities both because of their increased liability to trauma and because of the greater hydrostatic pressure to which their blood vessels are normally subjected Such hemorrhages appear to arise from capillary oozing rather than from macroscopic rupture of a larger vessel but they may attain almost any size Intramuscular hemorrhages are common at sites of particular mechanical stress Subperiosteal hemorrhages are relatively uncommon in adult scurvy but invariably accompany severe cases of infantile scurvy owing to loosening of the periosteal attachment which is a primary feature of

the functional pathology of the disease capillary bleeding *may dissect the periosteum* free over a large area Most commonly these subperiosteal hemorrhages are found at the lower end of the femur, the upper end of the humerus both ends of the tibia and at the costochondral junction of the middle ribs but they may be found in almost any location in severe cases as over the skull the clavicles, or the *scapulae*

The lesions of the gums will be described among the clinical signs Scurvy causes striking changes in the teeth separation of the odontoblast layer from the dentin and development of hemorrhages within the pulp cavity Although the teeth are capable of functional recovery the healing process is never anatomically complete so that histologic identification of an antecedent attack is possible throughout life

In growing tubular bones particularly in those having normally a rapid rate of growth, such as the middle ribs the histologic changes occurring at the cartilage shaft junction are characteristic the lattice of calcifying cartilaginous matrix is the site of numerous microscopic fractures the formation of trabecular bone by osteoblasts is in abeyance and the intervening marrow spaces at the end of the shaft are filled with a loose connective tissue framework con*taining hemorrhages and collections of fibrin* So greatly is the strength of the bone compromised by these processes that it offers relatively ineffectual resistance to the stresses accompanying normal activity, and the epiphyseal cartilage may be comminuted into the shaft or sheared off to one side carrying with it the periosteal attachment and a thin disk of calcified lattice

Symptoms —The symptoms of the disease begin as a rule insidiously with a feeling of general weakness and inadequacy negativism depression or even melancholia The normal degree of alertness is replaced by a disposition *to inactivity the patient* preferring to sit down or lie about The appetite fails and the taking of food is additionally hampered by painful *gums which* are disposed to bleed easily The skin is dry and rough at times dirty looking in more advanced stages so dark as to resemble the color found in hemochromatosis and it may *take on* a waxy appearance from retention of fluid In areas in which capillary pressure *is high as in the lower* extremities or in regions distal to constricting bands of clothing minute hemorrhages are to be seen in the hair follicles (piquete scorbutique)

Increasing mental depression accompanies progressive loss of muscle power The lips become cyanotic and the gums begin to show erosion of the mucous membrane at their *margins with formation of friable black* masses adherent to the teeth almost invariably these are accompanied by fetid breath The lower extremities develop swellings in the muscle masses particularly in the extensors and adductors of the thighs and in the calves and the knees are held in partial flexion, efforts toward full extension are accompanied by great pain There is increased swelling of the subcutaneous tissue of the feet particularly between the Achilles *tendon and the tibia Tenderness on deep* pressure may be elicited in any part of the limb Finally as a most important sign ecchymoses appear especially over the lower third of the thigh above the malleoli or on the dorsa of the feet Hemorrhage into the muscle masses or beneath the periosteum is generally accompanied by induration There may be either microscopic or gross hematuria

Not all of the symptoms mentioned are *necessarily of simultaneous* occurrence The mental depression which is of course relative and nonspecific is rarely absent but ecchymoses may occur in the absence of stomatitis and the disease may be clinically recognizable before extensive intramuscular or subperiosteal hemorrhages have *taken* place

With healing recovery occurs in more or less the following order stomatitis mental depression induration cutaneous hemorrhages and last discoloration of the skin

In particularly severe cases where healing does not take place the course is progres*sively downhill* The necrotic changes in the gums involve the alveolar process the teeth loosen and fall out often with uncontrollable *hemorrhage There may* be hemorrhage from the nose stomach or intestine or an extravasation of blood may suddenly appear without provocation *at some bizarre site* as in the orbit causing proptosis and ecchymosis of the eyelids Suppuration may develop in

any hematoma leading to the formation of huge abscesses The pulse becomes rapid and weak and the patient may suddenly die from relatively mild physical exertion or may expire from progressive prostration

In infants apathy and irritability alternate but anorexia is the rule In contrast to the afebrile state of older individuals elevation of temperature is almost always present Petechial hemorrhages are generally less conspicuous than in the adult The tenderness of the involved extremities and the changes in contour brought about by subperiosteal hemorrhages and epiphyseal infraction are often extreme On the other hand the oral signs are usually limited to swelling and purple discoloration of the gums around deciduous teeth which have already erupted or are about to erupt while the formation of large vegetations is rare and fetor exceptional

Anemia of some degree is the rule in scorbutic infants its intensity depending partly on the amount of blood lost and partly on the severity and duration of the disease process generally for deprivation of the vitamin retards new blood formation The leukocyte pattern is not affected in uncomplicated cases

Scurvy interferes with the healing of wounds and lowers the patient s resistance to superimposed infections of all sorts Of the latter the common complications are pyoderma wound infection oral sepsis pneumonia tuberculosis and especially in infants bacillary dysentery and diphtheria Scurvy often goes hand in hand with other deficiency diseases

Diagnosis —The diagnosis of scurvy is generally made on the history of an inadequate diet combined with the detection of some of the more obvious physical manifestations of the disease Subperiosteal hemorrhage supervening on mild or insignificant trauma is always highly suggestive other sites of bleeding are less specific in their import but any bleeding which does not depend on some demonstrable cause such as thrombocytopenia hemophilia or other defect of the blood clotting mechanism must give rise to a suspicion of scurvy Tenderness may be confined to the region of the long bones of the lower extremities or may at times be so capricious in its orientation as to bring the patient under suspicion of neurosis or even malingering The changes in the gums produced by scurvy may be simulated in thrombocytopenic purpura leukemia or mercurial poisoning

For the verification of the diagnosis roentgen examination of the long bones may be of immediate service provided the patient is young enough for growth of the bones to be still in progress The bone changes of infantile scurvy are pathognomonic and readily recognizable by one who has had experience in this field but in children and especially in young adults they are much milder are liable to be limited to the middle ribs where clearly defined photographs are technically difficult to obtain and only too often are subject to equivocal interpretation Subperiosteal hemorrhage is not ordinarily recognizable in roentgenograms until some days after the institution of effective therapy and until ossification has been resumed in the elevated periosteum

The importance of the demonstration of capillary fragility as an aid in the diagnosis of scurvy has in the past been somewhat overstressed An increase of capillary fragility accompanies most cases of scurvy arising as a result of gross errors of diet often preceding the appearance of other signs of scurvy Gothlin Dalldorf and others have demonstrated that subjects subsisting for long periods on a diet relatively low in vitamin C but still rich enough to obviate the development of frank symptoms and signs of scurvy show petechial hemorrhages when the difference of pressure within and without the vessel wall is insufficient to rupture that of a normal subject The ordinary tourniquet test of Rumpel and Leede increases the intravascular pressure above physiologic values while Dalldorf s suction method reduces the extravascular pressure to levels lower than atmospheric either technic is suitable Correlation between capillary fragility and chemical assay of ascorbic acid saturation is however far from close Since scurvy represents by definition the effect of ascorbic acid depletion this discrepancy suggests the possibility that capillary resistance may be dominated by some food factor other than vitamin C—Szent Györgyi s P substance perhaps The use of capillary fragility tests to support the diagnosis of scurvy

must be tempered by a full appreciation of their lack of specificity

Biochemical assay of the ascorbic acid stores has come to play a salient part in diagnosis especially in those cases in which the deficiency falls short of evoking characteristic physical signs of scurvy A plasma level close to zero accompanies all cases of untreated scurvy but identical values may be found in many subjects who are symptom free and who in consequence cannot in all truth be described as scorbutic The same may be said of low urinary concentrations Accurate evaluation of the degree of depletion may be achieved in any of three ways (1) simultaneous determination of the concentration of ascorbic acid in the patient s plasma and in the white cell and platelet layer of centrifuged blood (2) measurement of the plasma level in the fasting state and after intravenous or intramuscular administration of a test load of ascorbic acid (3) daily estimation of the total urinary excretion of ascorbic acid for several days following liberal dosage of the vitamin (of the order of 500 mg daily) Depleted stores are indicated in (1) by low values in both determinations in (2) by a low flat four hour curve in (3) by a delay of two days or more in the rise of urinary excretion

Since the response of a scorbutic patient to specific antiscorbutic therapy is usually prompt and dramatic and since the vitamin is available not only in the pure state but also conveniently in high concentration in orange juice and other vegetable sources the use of a simple therapeutic diagnostic test is legitimate and often decisive This makes it possible to explore a presumption of scurvy without the aid of accessory equipment and in favorable circumstances to lend strong probability to the diagnosis of scurvy once it has been taken into consideration It is when scurvy is not even thought of in the differential diagnosis that it is wrongly labeled as rheumatism myositis purpura or neurasthenia

Prognosis —Scurvy is readily amenable to treatment provided it be recognized in time and the prognosis generally depends on the complications—particularly on the infections—which the disorder has permitted to gain a foothold Of these tuberculosis is most to be feared Conspicuous as is the tendency to hemorrhage in the symptomatology of the disease fatal bleeding is rare unless as a result of surgical intervention from drainage of an infected hematoma or from the mistaking of a subperiosteal hemorrhage for osteomyelitis Under ordinary conditions of civil life deaths from uncomplicated scurvy are almost unknown

The deformities which accompany severe epiphyseal infractions in infantile scurvy are not of ultimate importance even though the healing process may cause the fragments to fuse in positions of faulty alignment, for with the resumption of normal growth the bone eventually attains anatomic as well as functional integrity

Treatment —The optimal intake of vitamin C for the normal subject has yet to be determined, dietitians argue that anything less than a state of repletion of the stores compromises the body s economy, but historic and general clinical evidence suggests that moderate unsaturation is not inconsistent with physiologic efficiency In a therapeutic test for diagnostic purposes the daily administration of 250 mg of ascorbic acid or about 16 ounces of fresh orange juice may be expected to dispel anorexia relieve mental depression to a considerable degree eliminate tenderness of the extremities and obviate the appearance of fresh capillary hemorrhages within from two days to a week provided these symptoms have their origin in a deficiency of vitamin C The total quantity of ascorbic acid required to re saturate a scorbutic patient varies from about 2 Gm up to ten or more times that amount differences depending in part on superior efficiency of vigorous dosage in the early stages of therapy as compared with smaller daily dosage over a more protracted period Absorption of orally administered ascorbic acid is usually complete or nearly so appreciable reduction in absorption occurring only in the presence of diarrhea or chronic disease of the intestinal tract Solutions of ascorbic acid are well tolerated in the blood stream as much as 6 Gm having been given in a single dose without adverse effect In spite of its acidity a 1 or 2 per cent solution of ascorbic acid in normal saline need not be buffered nor neutralized for intravenous injection

RICKETS

Definition—Rickets is a disease characterized chiefly by clinical and roentgenologic abnormalities of the skeleton which result from deficient deposition of lime salts in growing cartilage and in newly formed bone Except in rare instances to be enumerated later it is a deficiency disease which is caused by insufficient vitamin D during the age when growth is rapid Since the human organism is able to supply its need for the vitamin either by ingestion or by autosynthesis in the presence of a form of radiant energy contained in sunlight rickets is an expression of the combined absence of two factors one dietetic and the other environmental

Incidence—Since rickets is intimately related to the velocity of growth the disease primarily affects infants at the age when rapid growth is taking place Several months must usually elapse before the manifestations are perceptible clinically the disease is therefore rare in the early weeks of life and the majority of cases are diagnosed between the ages of four months and two years Under exceptional circumstances as when the mother suffers from a form of osteomalacia which results from lack of vitamin D Maxwell has shown that the disorder may exist at birth In the absence of prophylactic measures the incidence is extremely high during the susceptible age period The highest estimate is that of Schmorl who drew his conclusions from autopsies in Dresden between 1901 and 1905 94 to 98 per cent of infants between the ages of four months and one and one half years exhibited the disease A similar recent study by Park and Eliot in Baltimore indicated an incidence between 44 and 60 per cent between the ages of seven months and two years By means of x ray films Eliot and Souther investigated 1186 healthy children of mixed stock in New Haven The incidence of rickets of moderate or marked severity increased from the third month to a peak of 24 per cent at eighteen months and then declined to about 5 per cent at the third year Mild rickets which was demonstrated only by x ray affected 35 per cent of the infants between three and six months of age Combined incidence of mild and more advanced rickets at this early age period was about 50 per cent It is interesting to note that the occurrence of mild rickets coincides closely with the period of most rapid growth and that antirachitic measures are considerably less effective in removing the milder manifestations than in eliminating advanced rickets The question has therefore been raised as to whether mild rickets may not represent a physiologic manifestation of growth

The premature infant is particularly susceptible to the development of rickets The susceptibility is so extreme that one is almost justified in saying that moderate or severe rickets will develop in all premature infants unless preventive measures are instituted Twins belong in the same category

Rickets is predominantly a disorder of the temperate zone It is extremely rare in the far north where fish constitute the chief source of food the influence of sunlight prevents its occurrence in the tropics There is a striking seasonal incidence in the northern hemisphere the peak occurs during the winter and spring months when the rays of sun from the south are slanting Environmental variations in the amount of exposure to the sun also account for a greater prevalence in urban than in rural communities It is well known that the Negroes and Italians who dwell in the cities of the United States are unusually susceptible to rickets the susceptibility is accounted for at least in part by the dark pigmentation of the skin which offers a barrier to the penetration of radiant energy

Pathology—There are few diseases of which it is more true than of rickets that a knowledge of the pathology will bring an almost complete understanding of the clinical and roentgenographic manifestations The distinctive findings are limited to the skeleton and result chiefly from the failure of lime salts to be deposited in growing cartilage and in newly formed bone The uncalcified bone or osteoid tissue is morphologically similar to normal bone but because it lacks the elements essential for rigidity it is soft and easily distorted In health the formation of new bone is greatest at the ends of the long bones and at the costochondral junctions in these places rickets produces the greatest change Calcification about the proliferating cartilage cells fails capillaries from the shaft finding no supporting framework to guide the direction of their growth invade the region between cartilage cells and carry with them an envelope of connective tissue The cartilage cells failing to be destroyed by the normal process of metaplasia persist in scattered tonguelike aggregations which reach out from the cartilage into the shaft Thus the regular epiphyseal line of health disappears and in its place there develops a zone of varying width composed of osteoid and connective tissues blood vessels and cartilage cells This is the rachitic metaphysis The amount of calcified tissue which remains in the zone varies inversely with the severity of the rickets the width of the zone is roughly a measure of the duration of the disease The scattered lime salt deposits can be visualized in x ray films and give rise to the characteristic rachitic fringe at the ends of the bones The rachitic metaphysis is soft and in response to external stress the bone will bend in this region The constant pull of muscles and tendons tends to mushroom the firm epiphyseal cartilage into the metaphysis The resulting increase in circumference is the epiphyseal enlargement of rickets the hollowing out of the central portion of the metaphysis is responsible for the cup shaped deformity in x ray films Although the effect of rickets is most marked at the ends of the bones evidence of the disorder is also found in the shafts In healthy bone the process of destruction by osteoclasts and replacement by osteoblasts is continuous in rickets the process is similar except that replacement is by osteoid rather than by osseous tissue Trabeculae of bone come to be enveloped by *a mantle of osteoid tissue* as the disease continues the thickness of the mantle grows and the diameter of the bony core decreases Fractures are frequently found In x ray films the entire shaft appears rarefied This osteoporosis of rickets differs from that of disuse or of scurvy in that the trabeculae are not diminished in size and that the degree of penetration by x rays is determined solely by their lime salt content In health the production of cortical bone is a function of the periosteum In rickets the periosteum is sometimes excessively active in laying down concentric layers of lime deficient bone so that the shaft becomes considerably increased in thickness It is as though nature were attempting to compensate for the structural weakness

When under the influence of an antirachitic agent the rickets begins to heal the first demonstrable evidence of change results from calcification of the matrix about the more recently differentiated cartilage cells The new epiphyseal line which is formed is demonstrable by x ray and at once demarcates the distal end of the rachitic metaphysis The hiatus which remains between the new line and the shaft is obliterated more slowly as are also the signs of disease in the shaft itself

Etiology, Metabolic and Chemical Aspects—The changes in the bones in rickets are undoubtedly the result of a general disturbance in the metabolism of calcium and phosphorus The concentration in the serum of either one or both of these elements is always below normal while the rachitic process is advancing That this deficit in the serum is the chief cause of the skeletal lesions is shown by the fact that calcification of the intercartilaginous matrix of rachitic bone can be induced *in vitro* when a slice of the freshly excised tissue is immersed in normal serum The serum of healthy infants normally contains per 100 cc 10 to 11 mg of calcium and 4 5 to 5.5 mg of inorganic phosphorus According to Howland and Kramer the product of the calcium and phosphorus when both are expressed in milligrams per 100 cc furnishes an index of the presence or absence of rickets A product

less than 30 indicates the presence of rickets a product between 30 and 40 may or may not be associated with rickets a product greater than 40 indicates either that rickets is absent or that the disease is undergoing healing Although the practical value of the product is generally recognized Park has stressed the necessity of considering the rate of growth as an additional variable In most cases of rickets the serum calcium remains normal and the inorganic phosphorus alone is low When rickets is associated with tetany the calcium level is affected chiefly though both elements may sometimes contribute equally to the disturbance

The mechanism which controls the level of lime salts in the blood is not well understood although some facts about it are known Metabolism experiments have demonstrated that vitamin D has a profound effect on the absorption of these salts from the intestine During rickets the greater part of the ingested calcium and phosphorus is excreted in the stool even though the loss is rarely great enough to produce an actually negative balance With healing a strongly positive balance is established until the depleted skeleton has been replenished Thereafter the larger part of the excess phosphorus over that required for growth is excreted in the urine while the bowel continues to be the principal route for eliminating calcium That faulty functioning of the parathyroid glands plays a part in producing the abnormal blood findings in rickets is also highly probable These glands are hypertrophied in rickets the effect of the specific hormone in raising the level of calcium in the serum is well known

In rare instances rickets may be caused by disturbances which are unrelated to an inadequate supply of vitamin D The primary defect responsible for so called refractory rickets is not known Nevertheless success in therapy may follow the administration of vitamin D in doses which are many times as large as those commonly employed in the treatment of severe privational rickets Chronic renal insufficiency may be associated with rickets Apparently failure of the kidney to excrete phosphorus leads to the passage of this element into the bowel where it interferes with the absorption of calcium Hypocalcemia ensues and is followed by hypertrophy and hyperactivity of the parathyroid glands The excess of parathormone is responsible for the demineralization of bone In another rare type of rickets the disorder is associated with glycosuria and an excessive excretion of organic acids in the urine In other similar cases the urinary excretion of glucose is not observed and the process is attended by widespread deposits of cystine crystals throughout the cells of the reticulo endothelial system and occasionally by the excretion of cystine in the urine

Symptoms and Physical Signs—The accuracy which the x ray has contributed to the diagnosis of rickets has rendered it clear that the only characteristic signs are those which pertain to the skeleton Other manifestations such as irritability excessive sweating or muscular hypotonia are either difficult to evaluate or common to so many disorders as to be of no aid in recognizing the disease As a single exception the manifestations of tetany during infancy strongly suggest the presence of rickets Tetany however is a complex of symptoms which accompanies only a small fraction of all cases of rickets and which may occur occasionally from causes other than those responsible for rickets The skeletal signs of rickets are the combined result of the softened state of bone in the regions where growth is occurring and of the external stresses to which these regions are exposed Since age is a factor in determining the sites of rapid growth and since new stresses come into play when the child learns to sit and to stand it is apparent that the manifestations of rickets must vary in relation to the age at which they develop Long after the disease has ceased to be active the residual deformities are evidence of the age at which the process was most intense

Craniotabes may be the earliest demonstrable sign of rickets it is rare after the eighth or ninth month of life It develops in the occipital or parietal bones in one or more areas removed from the lambdoidal suture and invariably on that side of the head upon which the infant has habitually lain It is usually associated with softening along the suture line Craniotabes is often overlooked on routine physical examination its presence is detected by pressure with the

Pathology —There are few diseases of which it is more true than of rickets that a knowledge of the pathology will bring an almost complete understanding of the clinical and roentgenographic manifestations The distinctive findings are limited to the skeleton and result chiefly from the failure of lime salts to be deposited in growing cartilage and in newly formed bone The uncalcified bone or osteoid tissue is morphologically similar to normal bone but because it lacks the elements essential for rigidity it is soft and easily distorted In health the formation of new bone is greatest at the ends of the long bones and at the costochondral junctions in these places rickets produces the greatest change Calcification about the proliferating cartilage cells fails capillaries from the shaft finding no supporting framework to guide the direction of their growth invade the region between cartilage cells and carry with them an envelope of connective tissue The cartilage cells failing to be destroyed by the normal process of metaplasia persist in scattered tonguelike aggregations which reach out from the cartilage into the shaft Thus the regular epiphyseal line of health disappears and in its place there develops a zone of varying width composed of osteoid and connective tissues blood vessels and cartilage cells This is the rachitic metaphysis The amount of calcified tissue which remains in the zone varies inversely with the severity of the rickets the width of the zone is roughly a measure of the duration of the disease The scattered lime salt deposits can be visualized in x ray films and give rise to the characteristic rachitic fringe at the ends of the bones The rachitic metaphysis is soft and in response to external stress the bone will bend in this region The constant pull of muscles and tendons tends to mushroom the firm epiphyseal cartilage into the metaphysis The resulting increase in circumference is the epiphyseal enlargement of rickets the hollowing out of the central portion of the metaphysis is responsible for the cup shaped deformity in x ray films Although the effect of rickets is most marked at the ends of the bones evidence of the disorder is also found in the shafts In healthy bone the process of destruction by osteoclasts and replacement by osteoblasts is continuous in rickets the process is similar except that replacement is by osteoid rather than by osseous tissue Trabeculae of bone come to be enveloped by a mantle of osteoid tissue as the disease continues the thickness of the mantle grows and the diameter of the bony core decreases Fractures are frequently found In x ray films the entire shaft appears rarefied This osteoporosis of rickets differs from that of disuse or of scurvy in that the trabeculae are not diminished in size and that the degree of penetration by x rays is determined solely by their lime salt content In health the production of cortical bone is a function of the periosteum In rickets the periosteum is sometimes excessively active in laying down concentric layers of lime-deficient bone so that the shaft becomes considerably increased in thickness It is as though nature were attempting to compensate for the structural weakness

When under the influence of an antirachitic agent the rickets begins to heal the first demonstrable evidence of change results from calcification of the matrix about the more recently differentiated cartilage cell. The new epiphyseal line which is formed is demonstrable by x ray and at once demarcates the distal end of the rachitic metaphysis The hiatus which remains between the new line and the shaft is obliterated more slowly as are also the signs of disease in the shaft itself

Etiology Metabolic and Chemical Aspects —The changes in the bones in rickets are undoubtedly the result of a general disturbance in the metabolism of calcium and phosphorus The concentration in the serum of either one or both of these elements is always below normal while the rachitic process is advancing That this deficit in the serum is the chief cause of the skeletal lesions is shown by the fact that calcification of the intercartilaginous matrix of rachitic bone can be induced *in vitro* when a slice of the freshly excised tissue is immersed in normal serum The serum of healthy infants normally contains per 100 cc 10 to 11 mg of calcium and 4 5 to 5.5 mg of inorganic phosphorus According to Howland and Kramer the product of the calcium and phosphorus when both are expressed in milligrams per 100 cc furnishes an index of the presence or absence of rickets A product

chondrium and periosteum Another type of bony enlargement may result from excessive production of subperiosteal bone In the hands it leads to fusiform enlargement of the proximal and middle phalanges (*string of pearls* deformity)

Most conspicuous among the permanent malformations caused by rickets are the *bending* deformities To a large extent they originate when the disease continues to be active after the child has learned to sit The rachitic child shows little inclination to engage in the incessant activity which characterizes his healthy peers a posture once chosen becomes habitual and he sits for hours in essentially the same position The resulting stress on the skeleton leads to deformity not only because the bones are unusually yielding but also because the direction of application is unusually constant Commonly the child sits with thighs slightly spread apart and with one lower leg crossed over the other the hands are placed on the floor or on the thighs to assist the spine in holding the trunk erect The pull of gravity on the foot is augmented by that of the Achilles tendon so that the lower epiphyses of the tibia and fibula are displaced backward producing an angular deformity (*saber shin*) At the time of its origin the maximal convexity is just above the ankle With increasing age the bones grow in length beyond this site and ultimately the greatest bend is about one third the way up the shaft of the tibia Stress on the femur from the same posture leads to lateral and forward bowing and the femoral head is bent forward toward the shaft (*coxa vara*) That portion of the spine which is unsupported by the thorax is unusually vulnerable and marked lumbar kyphosis is not uncommon The combined deformities of lumbar kyphosis pot belly and flattened thorax produce a striking picture when the child is viewed in profile the outline is that of an erect truncated cone with the base at the level of the navel Less conspicuous bending deformities may develop in the upper extremities The humerus bows outward and the lower epiphyses of the radius and ulna may be bent to one side or the other depending upon the direction in which the hands are habitually turned When the child with rickets has learned to stand the stresses are altered Kyphosis is replaced by lumbar lordosis coxa vara is increased, and bowlegs or knock knees make their appearance The significant rachitic flattening of the pelvis probably begins during infancy from the force of gravity and is increased by the stresses applied during sitting and standing

Rickets leads to delayed eruption of the temporary teeth and is also associated with defects in calcification of the unerupted permanent teeth These defects are permanent and later appear as irregularities in the surface structure (*enamel hypoplasia*) Such teeth because of their defective structure are particularly prone to caries However it has not been demonstrated that an immediate relationship exists between vitamin D deficiency and dental caries

Diagnosis by X ray —The prevalent use of x rays has brought increased certainty to the early diagnosis of rickets and has provided the most satisfactory way of following the effect of therapy Much of our present knowledge would be lacking without them It is true that the very earliest signs of rickets which appear at the costochondral junctions cannot for technical reasons be visualized in roentgenograms but it is also true that clinical appraisal of departure from normal form in the rib cartilage junction is even more difficult A common clinical error is to diagnose rickets when no rickets is present

Experience has shown that the x ray changes characteristic of rickets are most easily recognized in pictures of the lower ends of the radius and ulna taken with the arm in complete supination The earliest changes are seen almost exclusively at the cartilage shaft junction The normally sharp termination of the shaft becomes blurred and finely irregular (*fraying*) the line of termination tends to become concave (*cupping*) the end of the bone is widened (*spreading*) and in some instances *cortical spurs* may be present at the lateral margins where lime salts have been deposited in the perichondrium which is adjacent to the periosteum Visualization of the very early changes depends upon faultless technic in making the pictures it is necessary to be sure that fraying has not arisen from slight movement on the part of the patient As the disease progresses to the moderate and

finger over the probable sites of involvement and the finding of relatively soft areas where the skull buckles and snaps back when the pressure is released The sensation is much the same as one experiences when pressing on the crown of a derby hat As the infant approaches the end of the first year of life craniotabes generally disappears even though the rickets continues to be active By this time however, the skull may present other evidence of the disease The eminences of the frontal and parietal bones become unusually prominent later are thickened into actual bosses which produce a square head (*caput quadratum*) Sometimes the eminences stand out as four rounded elevations separated by depressions which mark the lines of sultures (*hot cross bun* head *caput natiforme*) Rickets also results in delayed closure of the fontanels In severe cases the anterior fontanel may still be membranous at the age of three or four years

Fig 48—A rachitic child twenty months of age

Thoracic deformities belong among the early signs of rickets Rapid growth of the ribs during infancy renders the costochondral junctions particularly the sixth and seventh unusually susceptible Here rounded enlargements make their appearance and can be palpated along a line which extends downward and laterally on either side of the chest This is the *rachitic rosary* As the disease progresses the weakened metaphyses of the ribs yield to the force of negative pressure in the thorax and bend inward When the enlargments at the rib cartilage junctions are palpable externally they are even more prominent on the inner wall of the thorax Finally an external groove or depression develops along the line of the rosary At its lower end the groove merges with a girdle like depression (*Harrison's groove*) which appears when the ribs have bent inward along the attachments of the diaphragm Harrison's groove is generally accentuated by flaring of the lower ribs and distention of the abdomen Park and Howland have pointed out that the functional embarrassment which attends severe rickets of the thorax may actually endanger life The thoracic cage instead of expanding with each downward excursion of the diaphragm may even become more constricted pulmonary ventilation is further reduced by wide areas of atelectasis respiration is rapid and difficult and a relatively mild infection may have a fatal termination

Enlargements at other epiphyses develop more slowly than at the costochondral junctions but are often well developed before the end of the first year of life They are recognized most easily at the wrists and ankles where the subcutaneous tissue is relatively thin When the swelling is slight it is difficult to be sure that one is not dealing with the normal protuberances of the malleoli or styloid processes In examining the wrist the writer has made it a practice to palpate the dorsal as well as the lateral aspects since an abnormal swelling at the former surface is less liable to be confused with normal styloid processes Marked enlargement is now and again associated with an additional sign of abnormality namely *apparent duplication of the epiphysis* The sign is most conspicuous at the ankle where particularly the external but sometimes also the internal malleolus presents a double rather than a simple hump at the maximal convexity A pathologic specimen in the author's possession indicates that the lower or distal hump is caused by cartilage surrounding the nucleus of ossification and the upper or proximal hump by rachitic metaphysis that is there is a groove around the bone which marks the junction of peri

units per quart irradiated fresh milk and reconstituted irradiated evaporated milk furnish about 135 units per quart Since the average consumption of milk by an infant is less than a quart a day, the question is raised as to whether the lower dosages of vitamin are sufficient for prophylaxis Until experience has been amplified a final answer is impossible However it appears clear that the administration of any of the milks to full term infants is ample prophylaxis against the more severe types of rickets Milks which furnish 400 or more units per quart would seem to be as effective as the usual prophylactic dose of cod liver oil milks which provide only 135 units per quart allow the development of moderate rickets in enough instances to prevent complete confidence in their prophylactic efficiency

Although most cases of active rickets will respond satisfactorily to treatment with cod liver oil the time required for cure can be much shortened when one of the more powerful antirachitic agents is employed It is not practical to administer more than three teaspoonfuls of cod liver oil daily to an infant Viosterol is preferably prescribed in doses of from 4000 to 10 000 units daily (twenty to fifty drops of the official solutions) according to the severity of the disease This amount should be continued for two to three months and only slowly reduced to the usual prophylactic amounts When ever possible the effectiveness of treatment should be followed by serial x ray films taken at first at intervals of two or three weeks

Finally the prevention of rickets in the premature infant presents a special problem The unusual susceptibility of these patients renders large doses of vitamin necessary for adequate prophylaxis A satisfactory routine is to start with five drops of viosterol daily at the age of two weeks and increase the dosage by five drops at weekly intervals until thirty drops daily is being administered This level should be continued until the infant is seven or eight months of age when it may be replaced by the usual prophylactic regime

PELLAGRA

Definition —Pellagra is a noncontagious nonhereditary clinical syndrome affecting the skin alimentary tract and nervous system It is characterized by seasonal recurrences and relapses and may occur in any race and at any age

History—The term "pellagra" from the Italian pelle agra" meaning rough skin was first used in medical literature in 1771 by the Italian physician Frapolli who found the word in common use among the peasant population of Lombardy The authentic history of the disease begins somewhat earlier in northern Spain In the year 1735 Gaspar Casal, physician to King Philip V recorded his observations on mal de la rosa, a malady prevalent among the peasantry in the province of Asturias Twenty years later Antonio Pujati reported its presence in northern Italy and in 1784 a special hospital for the treatment of pellagrins was established at Legano by warrant of Joseph II of Austria During the nineteenth century the disease was observed in many other countries chiefly in France Egypt and Roumania In the United States of America, sporadic cases had been reported as early as 1864 from New York and Massachusetts but it was not until 1907 when Searcy called attention to the presence of a large number of cases of endemic pellagra in an asylum in Alabama that the seriousness of the situation in the southern part of the United States was appreciated Within the next few years many cases were reported from practically all southern and from many northern States

Incidence —Pellagra occurs in every country The incidence is high in Egypt United States of America Roumania Serbia Bulgaria Russia Italy and Spain Professor W H Wilson estimates that 30 per cent of the population of Egypt are affected with pellagra and the United States Public Health Service estimates that there are 400 000 cases annually in the United States of Amer

more severe stages the alterations become unmistakable The spreading increases the end of the shaft is hollowed out into a crater and the fraying widens into a fringe which may be 1 cm or more in width The visual izable evidence of disorder depends upon irregularly scattered areas of calcification throughout the rachitic metaphysis in the most severe form of rickets when calcification has ceased entirely the changes may be absent and the shaft appear to end abruptly as before the disease began In such cases the onset of healing is marked by the sudden appearance of all the characteristic features Severe rickets is also attended by equally distinctive x ray findings in the shaft These include marked osteoporosis either thinning or sometimes a lamellated type of thickening of the cortex and cloaking of the shaft with rarefied subperiosteal bone Change in the shaft however is rarely useful in establishing an early diagnosis and is a less sensitive index of the progress of successful therapy than is the cartilage shaft junction

The beginning of healing is heralded in x rays by the appearance of new deposits of lime salts in the zone between bone and cartilage Particularly prominent is the reappearance of an epiphyseal line at the proximal boundary of the cartilage At this stage the end of the bone is marked by two horizontal lines between which the area of greatest disorder is isolated The final obliteration of signs of the disease in x ray films may require many months

Prophylaxis and Treatment —The number of agents available for the prevention and cure of rickets has been increasing with bewildering rapidity The list now includes exposure to sunlight or to artificially produced ultraviolet light cod liver oil halibut liver (haliver) oil percomorph liver oil from an order of fishes which includes the tuna the swordfish the red snapper and the California sea bass viosterol concentrate of the nonsaponifiable fraction of cod liver oil crystalline vitamin D dissolved in propylene glycol and several types of antirachitic milk in which activation is accomplished by the inclusion of irradiated ergosterol in the diets of the cows (metabolized or yeast milk) by direct irradiation of the milk (irradiated milk) or by adding to the milk a homogenized concentrate of cod liver oil (vitex milk) All of these agents appear to be effective when given in adequate dosage they differ greatly in concentration of vitamin D in cost per unit of vitamin and in their associated content of vitamin A The list of agents is augmented by the availability of mixtures of the more potent remedies with cod liver oil These include cod liver oil with viosterol cod halibut liver oil and cod liver oil with percomorph liver oil

The student will avoid confusion if he remembers that the experience of clinicians regarding adequate dosage is far greater with cod liver oil than with any of the other preparations This experience has shown that a daily dosage of three teaspoonfuls of cod liver oil of average strength is sufficient to prevent rickets in the vast majority of infants Administration is begun in smaller dosage at the age of two or three weeks and increased slowly to the level mentioned The minimum U S P requirement for cod liver oil is a potency of 85 international (or U S P) units per gram the average cod liver oil on the market contains about 100 units per gram Three teaspoonfuls of this oil furnish about 1200 units This figure can be remembered as a rough guide in gauging the amounts of other antirachitic agents to be prescribed Several special brands of cod liver oil are available which are considerably more potent than the average article for instance that marketed by one firm contains 175 units per Gm The preventive dose of these special brands of oil is in the neighborhood of two teaspoonfuls per day Under particular circumstances the physician may wish to prescribe one of the more potent remedies for prophylactic purposes The official viosterol in oil contains 10 000 units per Gm or about 200 units per drop and the desired dosage is easily calculated In general however cod liver oil answers the need for an effective prophylactic agent and has the advantage both of being an excellent food and of supplying considerable amounts of vitamin A

A word must be added concerning the prophylactic value of the antirachitic milks As now marketed yeast milk contains about 435 units per quart milk with added concentrate of cod liver oil furnishes about 400

Prodromal Symptoms—The onset of pellagra is often so gradual that the earliest symptoms may not be noticed by the patient Early in the disease there is a loss of strength particularly in the legs a change in appetite and usually though not always a decrease in body weight There may be also a change in mood or in personality Pellagra in the early stages of the disease is often incorrectly diagnosed as neurasthenia

Skin—Pellagrous dermatitis is not always present but when observed may be readily diagnosed by its appearance symmetry, location and course Symmetric lesions may appear on any portion of the body, but are most common over sites of irritation such as the hands wrists elbows neck under the breasts knees feet and in the perineal region A sharp line of demarcation at the periphery of the lesion separates the affected area from the healthy skin In the majority of cases pellagrous dermatitis is restricted to the exposed parts of the body and the dermal lesions of pellagra often appear following exposure to sunlight The dermatitis begins as an erythema resembling sunburn As the disease progresses the area becomes reddish brown roughened scaly and keratotic vesicles and bullae may form Desquamation usually begins at the center of the lesion and the underlying skin appears red and thickened The intensity of the pigmentation and the thickening of the skin tend to increase with each recurrence of the disease after repeated recurrences the skin may become either permanently pigmented thick and roughened or thin and atrophic

Alimentary Tract—Both glossitis and stomatitis are early and common symptoms and are usually of such character as to be diagnostic of the disease In the beginning only the tip and lateral margins of the tongue are swollen and reddened If treatment is not given the swelling increases the red discoloration becomes more intense and deeply penetrating ulcers may appear along the sides and tip—rarely on top Frequently a thick gray membrane filled with debris and Vincent s organisms covers the surface The tongue is usually hypesthetic though it may be hypersensitive The buccal membranes the mucocutaneous surface of the lips the gums and the palate may likewise be affected The course of the stomatitis is similar to that of the glossitis A burning sensation of the tongue and of the mucous membranes of the pharynx esophagus and stomach is not uncommon this is often aggravated by hot or acid foods Ptyalism, nausea and vomiting may occur early but as a rule these are advanced symptoms of the disease About 50 per cent of pellagrins have no free hydrochloric acid even after histamine stimulation rennin and pepsinogen are likewise absent This achylia gastrica tends to persist during remissions The stools may be hard soft or watery but the odor is invariably foul Contrary to what is generally taught the bowels in the majority of mild cases act normally or are constipated Severe persistent diarrhea with several watery stools each hour tends to appear only in the more acute cases Abdominal distention discomfort and pain may be present at any time during the course of

Fig 49—Symmetric exfoliating lesions on elbows and dorsal surface of the hands of a pellagrin in relapse Multiple areas of ulceration and a few large bullae can be seen

ica It is believed that at least 10 per cent of the inmates of the insane asylums in the southern part of the United States were admitted because of pellagra

Etiology —For many years opinion in regard to the cause of pellagra was divided The two prevailing theories were (1) that it was a dietary deficiency disease and (2) that it was an infection in which diet played a more or less important role The spectacular improvement in so many pellagrins who receive intensive dietary treatment leaves no doubt that the disease may be explained on the basis of a dietary deficiency At the present time the consensus of opinion among investigators is that pellagra is a clinical syndrome caused primarily by a nutritional deficiency which may arise in one or more of the following ways (1) The person s diet may be inadequate in the antipellagric foods (2) His absorption may be impaired because of altered gastro intestinal function (3) His requirement for the antipellagric substances may be in excess of the amount supplied by a liberal well balanced diet

Goldberger advanced the theory that the pellagra preventive factor is a single substance vitamin B_2 (G) the thermostable portion of the vitamin B complex and until recently many students of nutrition accepted this theory It is now known that vitamin B_2 is not a single substance but is composed of a number of active principles Three of these namely nicotinic acid riboflavin and pyridoxine have been synthesized and thus far they are the only ones which have been found to play a role in human nutrition It has been shown that nicotinic acid is a specific curative agent for the mucous membrane lesions for many of the symptoms arising from the alimentary tract and for the mental symptoms of human pellagra and that it aids in preventing recurrences of these symptoms Its relationship to the dermatitis of pellagra has not been fully established Following the administration of nicotinic acid the concentration of cozymase and coferment (coenzymes I and II) in the blood and urine of pellagrins is increased from subnormal to normal values The increase in concentration of these coenzymes which are fundamental to cell respiration parallels the clinical improvement of the patient

Certain predisposing and precipitating factors often play a role in the pathogenesis of the disease Important among these are fatigue insomnia loss of teeth infections food idiosyncrasies, chronic alcoholism and diseases which cause improper ingestion assimilation or utilization of food Failure to consider all of the above mentioned conditions as underlying factors in the cause of pellagra has led to the designation of certain cases as pseudo pellagra ' pellagra sine pellagra postalcoholic dermatitis alcoholic pellagra and secondary pellagra Such terms are confusing and should be abandoned the disease is or is not pellagra

During the past twelve years from the study of over 10 000 pellagrins we have found that the inadequate diets of these persons predispose them simultaneously to a number of nutritional deficiencies and that pellagra frequently coexists with beriberi and riboflavin deficiency The diagnosis of pellagra therefore necessitates a thorough search for evidence of other deficiency syndromes and the institution of therapy specific for each deficiency

Morbid Anatomy —The most common gross findings are generalized emaciation of the body and atrophy of various organs Pellagra can be diagnosed at the postmortem table only when the characteristic oral and skin lesions persist In some cases the walls of the gastro intestinal tract may show swelling reddening and ulceration of any portion while in other cases the walls may be thin and atrophic The liver occasionally contains abnormal amounts of fat *Histologically* the skin lesions vary from atrophy to an intensive inflammatory reaction Similarly the microscopic picture of the intestinal lesions varies from atrophy to acute inflammation characterized by fibrin formation and collections of inflammatory cells When changes in the nervous system are demonstrable they are characterized by irregular areas of degeneration often involving the posterior and lateral columns of the spinal cord the posterior spinal ganglia and the Betz and Purkinje cells

Symptoms —These arise chiefly from the skin gastro intestinal tract and nervous system They vary greatly with each patient arising in some from only one of the systems and in others from two or more

the daily life of the patient must be properly regulated or he will fail to make satisfactory progress Without special treatment the death rate is more than 50 per cent in the severe cases Once the disease mild or severe has remitted *the prognosis is good* if no other predisposing condition or organic disease is present and provided the patient is cooperative and has perseverance and the capacity to continue treatment

Pellagrins who seem to be making satisfactory progress often become suddenly worse and die No single manifestation can be used as the sole indicator of the prognosis *In each case the immediate outlook is contingent* upon the general condition of the pellagrin and upon the presence or absence of other diseases

The outlook is most grave when severe mental symptoms hallucinations, violent motor excitement opisthotonos delirium rigidity tremors ankle clonus Babinski s sign or convulsions are present Extensive *and severe gastro-intestinal symptoms such* as intractable diarrhea and vomiting severe glossitis stomatitis and cachexia may also have an unfavorable effect on the course of the disease Refusal of food long continued abdominal distention and marked anemia should be regarded as ominous signs Pellagra is not usually accompanied by fever a temperature of 103° F makes for an unfavorable *prognosis The danger is increased if* chronic addiction to alcohol fatigue or surgical operations intervene The presence of infection darkens the outlook for just as infectious diseases predispose to pellagra so are pellagrins unusually susceptible to infections

Prevention —Pellagra can be prevented by the intelligent application of medical knowledge In order to eradicate pellagra people with organic disease those who are poor chronic alcohol addicts food faddists and those with improper dietary habits must receive special attention

Organic Disease —Organic disease often predisposes to pellagra by affecting the general nutrition and probably by increasing susceptibility Particular attention to the diet while the disease is being treated prevents the development of pellagra The incidence of pellagra is abnormally high among people having metabolic diseases chronic infections and diseases of the gastro intestinal tract

Poverty —Although pellagra often develops as the result of financial inability to buy proper food lack of knowledge in regard to *diet is an important contributing factor* If sufficient amounts of a well balanced diet are eaten regularly, pellagra will not develop Education of the poor in correct dietary habits is indicated so that those who can but do not may buy the inexpensive protective foods and those who cannot afford them may obtain protective substances such as yeast and wheat germ *through relief agencies*

Chronic Alcoholism —Chronic alcoholic addicts who do not eat adequate amounts of a well balanced diet develop pellagra Alcohol alone does not cause the disease but it often decreases the patient s appetite and diminishes his food intake This is easily understood when we consider that often the heavy drinker receives from 3000 to 4000 *calories per day from the alcohol alone* When alcoholic pellagrins are induced to stop drinking their appetites return they eat more food the disease is arrested and is not likely to recur Likewise alcoholic pellagrins who can be persuaded to eat large amounts of food do not have recurrences

Improper Dietary Habits —It is a popular fallacy to believe that our customary diets *are adequate Many people live on a diet* of narrow range too high in fats and carbohydrates because of custom preconceived ideas as to what foods are good for one and dependence upon the appetite as the guide in the proper selection of foods Education of the masses in the essential dietary requirements is imperative

Treatment —Pellagra is a systemic disease and must be treated as such early promptly intensively and persistently The essence of successful treatment is improved nutrition adequate rest and good medical and nursing care The methods must be adapted to the special needs of each patient and can be carried out most effectively if the patient is hospitalized and placed under the direct supervision of a doctor assisted by a nurse and a dietitian

Treatment of the Mild Case —Every adult with mild pellagra must ingest and retain a well balanced high protein diet of

the disease but are more severe after a large meal

Nervous System—Nervous symptoms are common but at the onset of the disease are often vague and ill defined The patient may complain of nervousness insomnia head aches dizziness muscular weakness and a bilateral burning of the hands feet and other parts of the body The tendon reflexes are frequently altered At first they may be exaggerated later decreased finally they may be absent The extremities particularly the legs may feel numb or become paralyzed Typical subacute combined de

Fig 50—Photograph showing symmetric dry scaly pellagrous dermatitis on the feet of a Negro Note the sharply demarcated borders and the hyperpigmentation at the periphery of the lesions

generation of the spinal cord with spasticity and ataxia is found Tremor and a spastic or ataxic gait is often associated with peripheral neuritis in the advanced cases

Mental Changes—Pellagrins are subject to periods of depression and apprehension and unless treatment is administered hallucinations confusion delirium and complete disorientation may develop Tremor jerky movements and rigidity of the body frequently accompany these mental symptoms If such cases are given early and intensive treatment the mental symptoms seldom persist but in the absence of treatment the patient is likely to become insane

Organs of Special Sense—Any of the organs of special sense may be affected, loss of taste and smell are common

Genito-urinary System—Burning on urination occurs frequently Libido is often decreased sterility is unlikely In the female acute pellagrous vaginitis with Vincent's infection is a usual finding Menstruation may be scanty or absent

Circulatory System—In the mild case a slightly subnormal blood pressure is often noted In the severe case there is an increased pulse rate lowered blood pressure and vasomotor collapse Syncope and sudden death frequently occur

Blood—The hemoglobin is less than 70 per cent in the majority of patients with severe pellagra The anemia is either macrocytic or microcytic in type

Temperature—The temperature of the mild uncomplicated case is usually normal an elevation of several degrees is serious as it denotes the presence of an infection or a severe type of the disease

Diagnosis—The typical case is easily diagnosed on the basis of a reliable history and careful physical examination The history is usually one of an inadequate or unbalanced diet high in carbohydrate and fat content Physical examination reveals the characteristic dermal and lingual lesions Atypical cases are many and can be recognized only by careful clinical study as there is no specific laboratory test for pellagra Were it not for the skin and oral changes characteristic of pellagra neither the typical nor the borderline cases could be distinguished from cases of chronic alcoholism beriberi pernicious anemia or sprue

Prognosis—Pellagra is always a serious disease A favorable course depends on an early diagnosis followed immediately by intensive and persistent treatment If untreated or incompletely treated it usually becomes chronic and continues through remissions and recurrences until either the pellagra itself or a coexistent or resultant secondary disease produces incapacitation or death The disease tends to increase in severity with each attack but the author has observed recovery after thirteen distinct relapses Even in cases with rare recurrences

PERIPHERAL NEURITIS —Ice bags and local medications containing phenol (1 per cent) and menthol afford temporary relief Physical therapy and splints are often beneficial For use of vitamin B_1 see Beriberi

BERIBERI

Definition—Beriberi is a clinical syndrome associated etiologically with a faulty food supply or an alteration of metabolism It is characterized clinically by multiple neuritis serous effusions edema muscular atrophy and cardiovascular changes Without being contagious it occurs sporadically and endemically and passes in great waves over the Oriental countries The disease is associated with ignorance and poverty and may appear in any race and at any age It is prevalent among infants whose mothers have beriberi

History.—Though the precise origin of the word beriberi is unknown the term undoubtedly arose from an Oriental language many centuries ago There is good reason to believe that the disease was described in the Neiching (2697 B C) Subsequent literature of the East contains many references to beriberi or to a disease so similar that it cannot be distinguished from it In 1642 Jacobus Bontius the first Occidental physician to describe the disease pointed out that the natives of Java called it beriberi During the nineteenth and twentieth centuries great interest arose in the recognition and prevention of beriberi and closely related diseases During this period of renewed clinical interest investigators applied dietary methods of prevention to special groups of the population with great success

Incidence—Beriberi occurs sporadically throughout the world It is prevalent both among infants and adults in the endemic areas of China Japan the Dutch East Indies Brazil India the Malay Peninsula and the Philippine Islands At times sudden outbreaks of the disease occur in these countries and in prisons and asylums of the Western World

For many years it was believed that beriberi seldom occurred in the Western Hemisphere Recent studies show however that beriberi (nutritional peripheral neuritis) is much more prevalent than is commonly supposed Its incidence is high among pellagrins alcoholic addicts and pregnant women It is frequently associated with organic disease and often coexists with other nutritional deficiencies

Etiology.—The results of clinical and experimental studies point to a definite relationship between an unbalanced diet abundant in decorticated cereals and the development of beriberi Such diets are known to be deficient in vitamin B_1 Although it has not been proved that one specific factor is the sole cause of the disease clinical and experimental studies leave no doubt that persons with beriberi are greatly benefited by vitamin B_1 therapy

It appears that man cannot synthesize vitamin B_1 nor can he store it to any great extent The length of time a deficiency must exist or the degree to which it must be present before clinical evidence of the disease

at least 4000 calories per day, the diet should include 1500 cc sweet milk ½ pound lean meat or liver, and eight eggs Additional milk should be given instead of water except in very dehydrated cases Water tends to decrease the amount of food ingested, the milk will not only supply fluid but will also be an additional source of nourishment Diets abnormally high in carbohydrate or fat content are contraindicated The diet should be supplemented especially at night by large amounts of a potent specific therapeutic agent prepared by a reputable concern When administered by mouth dry powdered brewers yeast (30 Gm three times daily) crude liver extract (30 Gm three times daily) wheat germ (60 Gm three times daily), or nicotinic acid or nicotinic acid amide (10 doses 50 mg each daily) are effective The amide is preferable to nicotinic acid when one wishes to avoid vasodilating reactions

Treatment of the Severe Case—The severe case that is one with central nervous system involvement intractable diarrhea persistent vomiting marked anemia a pulse rate exceeding 120 or a temperature of 103° F must have immediate supportive as well as antipellagric therapy As in the mild case success of treatment depends upon improved nutrition adequate rest and appropriate medical and nursing care The food intake must be increased to at least 4500 calories per day The specific therapeutic agent must be administered in amounts three times as large as those used for the mild case Absolute rest in bed is imperative Parenteral liver extract (probably the crude preparation is more efficacious than the refined) given intravenously or intramuscularly in doses of 20 cc three to five times daily in addition to the wheat germ yeast or liver extract by mouth is often beneficial especially to patients with persistent vomiting or diarrhea Nicotinic acid orally (50 mg ten times daily) or parenterally (25 mg in physiologic solution of NaCl two or three times daily) is astoundingly effective Healing of the oral and dermal lesions even in the most severe cases usually begins within seventy two hours after treatment is begun and the relief of the psychoses of pellagra is spectacular

Special Treatment of Symptoms—Symptomatic treatment often aids in remitting the disease Exacerbation of the stomatitis vomiting diarrhea and abdominal pain must not deter the physician from continuing the administration of proper diets specific therapeutic agents and indicated symptomatic therapy

Oral Lesions—The use of a mouth wash is beneficial The teeth should be brushed gently to avoid severe hemorrhages

Skin Lesions—Potassium permanganate solution (1 5000) used as soaks offers some relief and in the moist type of lesion diminishes the possibility of secondary infection

Diarrhea—Tinctura opii 2 cc., can be given every four hours unless symptoms of overdosage appear This is sometimes beneficial and is particularly indicated whenever an analgesic is required The severe case should receive fluids by a parenteral route The administration of nicotinic acid is effective

Vomiting—Absolute rest in bed and feedings of an iced fluid such as eggnog ginger ale or malted milk in small quantities (10-15 cc) at intervals of ten to fifteen minutes are necessary and should be continued until the patient has not vomited for twelve hours Either yeast wheat germ or liver extract should be added to these feedings in amounts of 4 to 5 Gm until the daily requirement has been given In the more severe case parenteral liver extract must be given immediately and continued until the patient is able to retain the required amount of the recommended diet together with any one of the potent specific therapeutic materials

Abdominal Pain—The pain often increases after meals thus discouraging the patient from eating Codeine will relieve this and should be used generously

Anemia—If the hemoglobin is below 50 per cent blood transfusions should be given After recovery has started large doses of iron should be administered

Fever—Alcohol sponges are indicated when the temperature is more than 103° F

Tachycardia—Patients with tachycardia must have constant rest

Mental Symptoms—Large doses of nicotinic acid result in spectacular relief of the mental symptoms and its use is indicated instead of sedatives

He is weak has a rapid, irregular pulse edema of the legs, and usually dies suddenly or is rapidly and completely cured by treatment

In contrast the onset in the adult is usually insidious and the prodromata are vague and general Lassitude general itching, dyspepsia tachycardia fatigue on exertion and tenderness of the muscles occur early After a variable period of time the symptoms can be associated with degeneration of the nervous system alteration of the gastro intestinal tract the presence of edema and serous effusions or enlargement and dilatation of the heart When the disease affects chiefly the peripheral nerves it is commonly called the dry type when it is especially characterized by acute cardiac symptoms it is known as the fulminating type and when it is associated primarily with edema and serous effusions it is referred to as the wet type Beriberi strikingly selects the vagi the peripheral nerves of the extremities and the vasomotor system

All symptoms are not necessarily present in a given patient and the order of their appearance may vary A patient with predominating cardiac symptoms may suddenly develop gastro-intestinal symptoms such as a distaste for food vomiting or diarrhea the patient with gastro intestinal distress may suddenly display such myocardial symptoms as dyspnea precordial pain and circulatory failure Either or both of the foregoing types may have or may develop peripheral neuritis and conversely a patient with peripheral neuritis may have cardiorespiratory or gastro intestinal symptoms Serous effusions and edema may precede accompany or follow the cardiac gastro intestinal or nervous symptoms

The symptoms subside slowly in the adults who recover many months may pass before there is a restoration of function if indeed complete restoration ever does take place Often after the active phase of the disease disappears residual paralysis muscular atrophy and cardiac enlargement remain for long periods of time

Nervous Symptoms —The chronic cases have involvement of the nervous system The early course is characterized by tingling of the hands and feet and by weakness of the legs The clinical manifestations are caused by an ascending symmetrical peripheral neuritis The deep reflexes of the extremities at first increase later diminish and finally are absent Tenderness in the calf muscles and sharply defined patches of anesthesia and numbness often appear early This process affects particularly the extremities and sometimes the diaphragm producing wasting of the muscles contractures ataxia lack of coordination and dyspnea Sensations of touch pain and temperature are usually decreased but at times they may be increased Anxiety states and mental confusion are common manifestations

Cardiorespiratory Symptoms —When the disease is characterized especially by cardiac symptoms (fulminating type) the adult patient usually dies suddenly and without a history of prodromal symptoms Occasionally however a person with gastro intestinal and neurologic symptoms suddenly develops the fulminating type of the disease The cardiac symptoms are always striking The most common ones are palpitation tachycardia dyspnea lowered blood pressure cardiac murmurs changes in the electrocardiogram and paralysis of the diaphragm Before death there is nearly always cardiac enlargement and dilatation pulmonary congestion edema cyanosis and vasomotor collapse

Digestive Symptoms —Frequently there is nausea vomiting and epigastric distress These symptoms are especially prominent in the acute fulminating type and are often found with cardiac decompensation

Other Symptoms —Edema is the most striking feature of many cases It usually begins in the legs and may progress until the whole body becomes involved Sometimes a typical case with the body bloated from anasarca appears emaciated following diuresis Polyuria is marked as the edema disappears but the amount of urine is decreased when the edema is increasing Hydropericardium and effusions into various serous cavities are common and a low serum protein can be demonstrated frequently At times the organs of taste smell hearing and sight are involved Libido decreases Anemia may appear in the later stages of the disease

Diagnosis —The typical case can be read

appears is not known Clinical studies show that the depletion period is extremely variable ranging from a few weeks to months or years They show also that certain factors predispose to and precipitate the development of the disease Prominent among these are increased physical exercise fevers hyperthyroidism and other conditions which are accompanied by an increased metabolic rate pregnancy and lactation digestive disturbances and chronic

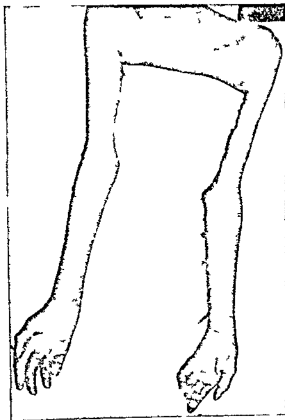

Fig. 51 —Muscular atrophy of the upper extremities in a beriberi patient with severe peripheral neuritis Compare the wasting of all muscle groups in the arms with fairly normal muscles of the shoulder girdle and neck

debilitating diseases which cause improper ingestion assimilation or utilization of food

At the present time the precise manner in which a deficiency of vitamin B_1 operates to produce the symptoms of beriberi is not understood It has been shown however that cocarboxylase (thiamin pyrophosphate) has antineuritic properties and that it is a fundamental enzyme which plays a prominent role in oxidation and reduction

There is considerable evidence that other nutritional diseases often coexist with beriberi Persons with beriberi frequently have a deficiency of nicotinic acid and riboflavin and symptoms which arise from these deficiencies are benefited by the administration of these synthetic chemical substances The number of factors involved in the development of the disease is not known and knowledge concerning the physiologic mechanism is incomplete Nevertheless the synthesis of vitamin B_1 (thiamin), nicotinic acid and riboflavin has stimulated investigation and during the next few years much of the confusion over the relationship between the various symptoms of beriberi and between beriberi and other diseases should be eliminated

Morbid Anatomy—Postmortem examinations are of little value in making a diagnosis or in explaining the pathologic physiology of the disease The findings are not constant but the process in general is one of degeneration affecting especially the myocardium the gastro intestinal tract and the nervous system The most common gross findings are emaciation of the body and atrophy of the muscles particularly in the legs The body is often edematous the heart is dilated and hypertrophied and serous effusions and chronic passive congestion of the viscera are commonly observed Microscopic studies show diffuse edema in various tissues and degeneration of the involved nerves muscles and myocardium Degeneration of the nerves varies from slight alteration to complete degeneration of the myelin and axis cylinder The affected muscles show a diffuse parenchymatous degeneration with loss of striations and hyaline and fatty changes The cardiac muscle fibers are often fragmented and contain hyaline and fatty material Postmortem findings in infants dying of beriberi are practically identical with those found in the adult The degenerative changes in the nerves are however less striking in the infant

Symptoms—Beriberi may be an acute or chronic disease In the infant it is nearly always acute in the adult it is nearly always chronic The symptoms of infantile beriberi appear identical with those of the fulminating type in the adult Infantile beriberi is characterized by a rapid onset with diminished urinary secretion constipation rigidity of the body and cyanosis The child has a peculiar whine and cries most of the time

for every case in which the diagnosis of beriberi is established It may be administered intravenously intramuscularly or orally Parenteral administration is recommended in severely ill cases especially when vitamin B_1 deficiency is associated with severe gastro enteric disturbances or with cardiac failure In such cases 30 to 50 mg should be given intravenously in sterile physiologic saline twice daily For the average case the parenteral administration of 10 mg twice daily is adequate Oral administration of 5 to 10 mg twice daily is sufficient for the mild case Brewers yeast wheat germ and tikitiki (an alcoholic extract of rice polishings) are effective therapeutic agents in the average case of vitamin B_1 deficiency The usual dose of brewers yeast and wheat germ is 6 ounces and of tikitiki 3 ounces The yeast and wheat germ are best tolerated if given in iced milk or egg nog at frequent intervals All persons who have a vitamin B_1 deficiency should be given a well balanced high caloric diet including foods rich in vitamin B_1 These foods are whole grain bread and cereals legumes lean pork liver heart kidney and milk All patients whether the disease is mild or severe should be kept at complete rest until convalescence is well established

For infants with beriberi the parenteral administration of from 5 to 10 mg of crystalline vitamin B_1 is recommended After convalescence is established the same amount may be administered orally If crystalline vitamin B_1 cannot be procured an alcoholic extract of 100 Gm of rice polishings (tikitiki) may be given daily If the child s mother has latent or manifest beriberi cow s milk should replace breast milk

RIBOFLAVIN DEFICIENCY

The importance of riboflavin in human nutrition was observed independently by Sebrell and Butler and Vilter Vilter and Spies Riboflavin deficiency occurs in either sex at any age and is common in persons who subsist over a considerable period of time on a grossly inadequate diet It tends to occur in the spring and to disappear during the summer months

Diagnosis depends upon the recognition of characteristic angular stomatitis associated with transverse fissures in the corners of the mouth Another lesion occurring less frequently is the accumulation of greasy seborrheic material around the alae nasae and occasionally around the eyes and on the ears In the Nutrition Clinic of the Hillman Hospital Birmingham Alabama we have observed over 5000 persons with riboflavin deficiency In our experience we have found that diagnosis depends upon the recognition of certain symptoms and their response to the administration of synthetic riboflavin or substances containing riboflavin The symptoms characteristic of riboflavin deficiency are angular stomatitis associated with transverse fissures in the corners of the mouth and lips (Fig 52) and an abnormal shiny redness of the mucous membranes of the lips a sharkskin appearance of the skin around the alae nasae eyes and occasionally over the ears and malar prominences ocular symptoms characterized by bulbar conjunctivitis lacrimation burning of the eyes and failing vision and invasion of vessels of the cornea These symptoms disappear within four to six days following the

ily diagnosed by means of a reliable dietary history and by the presence of certain characteristic physical findings Almost without exception the history reveals that adults who develop beriberi have subsisted on a monotonous diet abundant in carbohydrates (chiefly milled rice wheat or corn) The physical findings are an enlarged heart peripheral neuritis edema and tenderness and atrophy of the muscles Infants who are restricted to the milk of women with beriberi usually develop the disease during the first three months of life The diagnosis is made on the following objective findings constipation diminution in the volume of urine rigidity of the body, irritability, a rapid and irregular pulse weakness edema cyanosis and a peculiar whine

While the atypical or mild cases occurring in infancy or later are probably more common than the typical ones the manifestations in such cases vary greatly and the disease is not easily recognized Since there is no specific laboratory test for beriberi it is often necessary to exclude the possibility of various types of heart disease diphtheria nephritis tabes alcoholism lead and arsenic poisoning pellagra scurvy and sprue before a positive diagnosis of beriberi can be made

Prognosis—No disease requires more conservatism in making a favorable prognosis than does beriberi for a patient who seems to be recovering may suddenly develop cardiac symptoms and die The mortality rate is variable being around 5 per cent in the mild cases and reaching well over 50 per cent in the more severe ones The ultimate prognosis is dependent upon the age and general condition of the patient and upon the severity and duration of the disease In general patients with acute cardiac symptoms are least likely to survive If the adult is left untreated eventually incapacitation or even death is to be expected If however the disease is recognized and treated early the outlook is good provided the patient can and will follow recommendations Recovery is rapid and complete in infants who are given early and persistent treatment

Prevention—Prevention in the adult or infant is dependent upon the ingestion assimilation and utilization of sufficient quantities of a well balanced diet Beriberi would practically disappear if it were possible to make proper diets available to all We cannot hope however to achieve this ideal in the immediate future as its fulfilment is dependent upon educating the masses and raising their economic level The most logical means of ending beriberi as a world problem in the near future would be to pass and enforce a law preventing the overmilling of rice wheat and corn Grain products have long been the principal component of the poor man s diet Overmilling of the cereals has deprived the finished product of much of its natural mineral and vitamin content Consequently the foods which may constitute the major part of the diet of persons most in need of improvement in their nutritional status are nutritionally inferior The enrichment of flour and bread in this country is a step forward in improving the diets of these persons Until such time as proper diets are available to all people or until a law prohibiting the sale of overmilled cereals is passed and enforced the incidence of beriberi can be greatly decreased by the application of the following recommendations

1 Whole grain or enriched flour and bread should be substituted for the highly milled products

2 Foods must not be overcooked as excessive heat destroys vitamin B_1 The common habit of adding soda during the cooking process is detrimental and should be discontinued Foods should be cooked in as little water as possible and the water in which they are cooked should be used in soups or broths rather than discarded

3 Lean meat milk eggs fresh vegetables dried vegetables and nuts should make up at least 50 per cent of the daily diet

4 Any one of the following relatively inexpensive supplements is helpful in preventing beriberi and should be added to the daily diet whenever possible dried brewers yeast (1 ounce) wheat germ (2 ounces) or tikitiki (1 ounce) Infants are given indirect protection by preventing the disease in mothers and can be given additional protection by supplementing their daily diet with an alcoholic extract of 40 Gm of rice polishings (tikitiki)

Treatment—Crystalline vitamin B_1 (thiamin hydrochloride) is recommended

10 mg of thiamine 50 mg of niacin, 5 mg of riboflavin and 75 mg of ascorbic acid When we find that the symptoms of one deficiency disease predominate we add to this formula more of the vitamin specific for the predominating deficiency In the case of beriberi 10 mg of thiamine are added daily in riboflavin deficiency, 5 mg of riboflavin twice daily in scurvy 100 mg of ascorbic acid three times a day and in mild pellagra 50 mg of niacin amide three times a day If the pellagra is severe the patient is given 150 mg of niacin amide three times a day in addition to the basic formula When the patient is moribund it may be necessary to resort to parenteral injections in order to prolong and indeed even to save life When large amounts of *d* glucose are injected daily we recommend the inclusion of 20 mg of niacin amide 7.5 mg of riboflavin and 5 mg of thiamine In a few instances we have found it desirable to inject 50 mg of ascorbic acid in physiologic solution of sodium chloride

Dried brewers yeast powder liver extract wheat germ and rice polishings are excellent therapeutic agents for the treatment of diseases arising from a deficiency of the B complex vitamins These substances are particularly valuable in that they contain significant amounts of protein and other essential nutrients and probably vitamins of the B complex as yet unknown The amount administered depends upon the severity of the disease We usually give daily from 120 to 180 Gm of dried brewers yeast powder or oral liver extract from three to four doses of 20 cc of parenteral extract or from 150 to 300 Gm of wheat germ For prevention or supplementary treatment smaller doses are used

SPRUE

Definition —Sprue is a chronic afebrile disease with a marked tendency to remissions and relapses When *fully developed* it is characterized by glossitis gastro intestinal indigestion meteorism diarrhea with the passage of voluminous fatty frothy foul smelling stools great loss of weight generalized muscular wasting with asthenia and (in adults) by a macrocytic hyperchromic anemia

History —The earliest clearly recognizable description of the sprue syndrome was given by Aretaeus the Cappadocian in the second century A D Sprue is the English form of the Dutch word 'Sprouw meaning aphthous stomatitis The term was first used by Vincent Katelaer in 1669 in describing a disease among the Belgians characterized by aphthous stomatitis and by fecal discharges so copious "that several basins or pots scarcely hold these accumulations" William Hillary's description of sprue as observed in the Barbados was first published in 1759 The modern conception of sprue however dates from the publications of Manson and of Van der Burg in the same year 1880 Samuel Gee in 1888 gave a brief but classic description of a wasting disease of early childhood associated with copious fatty stools, which he called "the coeliac disease" He indicated however that it might occur in patients of any age

Incidence —The disease has long been known as tropical sprue because of its endemicity in certain tropical regions For North American physicians however it is important to emphasize that the sprue syndrome occurs in the United States *both north and south and that it is often wrongly diagnosed* Recent investigations indicate that tropical sprue' nontropical sprue and 'celiac disease are manifestations of the same morbid condition

Etiology —The exact etiology is unknown but the generally accepted view today is that the sprue syndrome is the result of nutritional deficiency and the remarkably beneficial action of liver in the treatment of the disease strongly supports this conclusion It is possible that the deficiency in sprue may arise in four ways (1) by a dietary deficiency of the extrinsic factor (to use the terminology of Castle) (2) by a defect of gastric digestion due to lack of the intrinsic factor (3) by poor absorption from the intestine and (4) by deficient storage by the liver A combination of several of these defects may exist Recurrent attacks of sprue often are associated with pregnancy

By feeding to swine a diet deficient in certain food factors Rhoads and Miller have produced a disease which very closely simulates sprue Ashford ascribed the onset of

administration of adequate amounts of riboflavin

Treatment —In the average case, the administration of 5 mg of synthetic riboflavin t i d was followed by the disappearance of the lesions within three to six days Each of two patients who were given 2 mg of synthetic phosphoric acid ester of riboflavin t i d showed similar improvement within six to eight days In the above cases Ashe and Spies found that the daily excretion of flavin (determined as riboflavin) was 18 per cent below normal Diminished output of

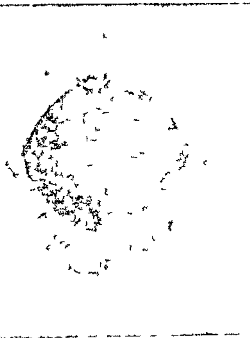

Fig 52 —Cheilosis (angular stomatitis) a characteristic lesion of riboflavin deficiency appeared in this young woman following cyclic vomiting

flavin has been observed in other patients who have not had the typical lesions described above Following the administration of riboflavin the level in the urine rises These studies suggest that in persons subsisting on inadequate diets riboflavin deficiency is not uncommon Our figures indicate that the riboflavin requirement for an adult is approximately 3.5 mg daily

Comprehensive reviews of the physiology and pathology of riboflavin deficiency and on the chemical nature of riboflavin have been published and its importance in human nutrition has been established but at the present time the exact mechanism of its action is not understood Nevertheless it is known that the lesions of riboflavin deficiency disappear and the patient has an increased feeling of well being following the ingestion of an adequate well balanced diet the administration of brewers yeast or synthetic riboflavin

MIXED DEFICIENCY DISEASES

Diets that fail to supply one nutrient in adequate amounts are deficient in others and every method of study has indicated the predominance of mixed rather than single deficiencies Accordingly a person may develop a number of diseases simultaneously although diagnostic evidence of only one may be apparent at the time he is examined by the physician The basis of treatment of all patients with deficiency diseases is a diet that supplies liberal amounts of all the essential nutrients In many instances however food cannot be consumed in sufficiently large amounts to supply the patient with the quantities of nutrients needed to restore him to health Too often it is forgotten that we must treat the patient rather than hi disease and that treatment must be adapted to the individual case Even a liberal well balanced diet should be supplemented with all the vitamins known to be essential for human nutrition They may be given as crystalline vitamins as concentrates or in the form of therapeutic materials such as dried brewers yeast or liver extract

In treating the clinical syndromes of beriberi pellagra riboflavin deficiency and scurvy we give a basic formula consisting of

in sprue from two to three times the normal amount is found Frequently it can be demonstrated microscopically by staining with Sudan III but only exact quantitative analysis can be depended upon to reveal the excess of fat Although the total fat of the stool is greatly increased, the end products of fat digestion are not relatively altered from the normal indicating normal lipolysis The pancreatic enzymes are present in normal amounts in the duodenal contents The difficulty would seem to be one of assimilation rather than of digestion and several observers have shown that there is a low blood fat curve after feeding fats similar to the low blood sugar curve after the ingestion of glucose The loss of nitrogen is slight and sprue patients digest and absorb proteins readily An excess of calcium may be excreted in the stools producing low serum calcium values Serum phosphorus is also low but in this case the excessive excretion is by way of the urine

Blood Sugar Curve—Thaysen first observed that in patients with sprue following the ingestion of 1.5 Gm of glucose per kilo of body weight a low blood sugar curve was a frequent finding whereas less than 5 per cent of normal individuals show this type of curve The test is very valuable and deserves the widest application It offers an easy and reliable aid in the differentiation of sprue from pernicious anemia pancreatogenous steatorrhea and tabes mesenterica diseases with which it is most liable to be confused In 54 sprue patients observed at Duke Hospital none of whom had been in tropical countries and only one of whom had even lived outside the state of North Carolina the maximum rise in the blood sugar curve following the ingestion of 1.5 Gm glucose per kilo of body weight was 39 mg per cent the minimum 4 mg per cent and the average 20 mg per cent In ten pernicious anemia patients similarly tested none showed a rise of less than 40 mg per cent and the average rise was 59 mg per cent In pancreatogenous steatorrhea the blood sugar curve is diabetic in type Glucose given *intravenously* (0 2 Gm per kilo of body weight) produces a normal response in the blood sugar curve

Blood—In early sprue a mild hypochromic anemia may be found but this soon changes to a macrocytic hyperchromic anemia which cannot be distinguished from the blood picture of pernicious anemia Bone marrow, obtained by sternal puncture, is

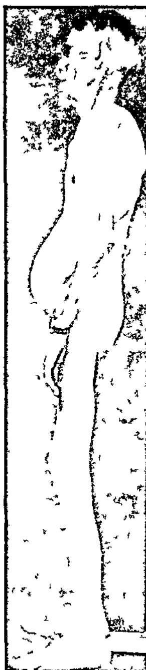

Fig 53—Sprue cachexia

indistinguishable from the hyperplastic megalocytic marrow of pernicious anemia As the patient improves the blood becomes either normal or hypochromic In infantile

the disease to the preponderance in the diet of carbohydrate and fatty foods and a deficiency in proteins, a view which has been widely adopted He thought however that this nutritional imbalance led to gastro intestinal conditions favorable to the growth of a yeastlike fungus *Monilia psilosis* which in turn aided in producing the clinical picture known as sprue The studies of Castle and Rhoads on sprue in Puerto Rico do not substantiate Ashford s theory of the pathogenic action of *Monilia* and there is no acceptable evidence that sprue is an infectious disease

Morbid Anatomy —There are no pathologic changes characteristic of sprue The gastro intestinal tract frequently shows marked atrophy of the mucosa and thinning of the walls The colon is often greatly dilated The parenchymatous organs especially the liver and spleen are smaller than normal and the storehouses of fat are remarkably depleted The disease literally dissects the patient

Symptoms —All the symptoms of sprue are due to dysfunction of the gastro intestinal tract In the beginning the patient suffers from recurring attacks of indigestion with flatulence and diarrhea of varying severity alternating with constipation The tongue and mouth may or may not be sore In early or mild cases the episodes of diarrhea may be so slight that only questioning brings them to light The sprue patient may pass but one large fluid foul smelling stool daily A carefully taken nutritional history may reveal that the patient has subsisted upon a badly balanced diet composed of an excess of carbohydrates and fried foods and a deficient amount of meats Not infrequently the indigestion and diarrhea have caused a further limitation of protein intake Defective teeth and poor oral hygiene are common causes of a poor or perverted appetite and idiosyncrasies of diet once established often are fixed by habit However no history of dietary peculiarities can be obtained in some sprue patients Gradually the sense of well being is lost and the patient feels generally miserable Such patients are very commonly diagnosed as neurasthenic and their gastro intestinal symptoms explained as due to a neurosis

If the nutritional deficiency is unrecognized and untreated the complete picture of sprue gradually develops with exacerbations and remissions characterizing its course The patient is now no longer ailing but actually ill The entire gastro intestinal tract shows evidence of disease the tongue and mouth often become sensitive to hot or seasoned foods and crops of small very sensitive aphthous ulcers may appear on the buccal mucous membranes Epigastric distress vomiting and intestinal colic are complained of and the stools become more frequent, bulky light in color frothy and foul smelling The diarrhea is especially troublesome in the early morning several voluminous stools being passed before breakfast The appetite fails and the patient emaciates rapidly It is not uncommon for one third or one half of the normal weight to be lost in striking contrast to pernicious anemia in which the loss of weight usually is moderate

In fully developed sprue the patient often presents the picture of an asthenic mentally depressed unhappy individual with almost complete anorexia The skin is rusty grapefruit colored and occasionally symmetrically pigmented the panniculus adiposus gone, the abdomen protuberant and the bones show through as though the patient were a living skeleton The tongue is beefy red and sore showing marked papillary atrophy Paresthesia of the hands and feet is quite common and in rare instances subacute combined degeneration of the spinal cord has been observed

Diagnosis —Sprue may occur at any age The infantile form which begins as a rule in the second year is known as celiac disease or chronic intestinal indigestion and owing to generalized malnutrition with deficiency of calcium and phosphorus dwarfism rickets and tetany are not infrequent features of the clinical picture Osteoporosis and tetany are seen in adult sprue Older patients who have suffered from sprue in infancy or early childhood frequently show dwarfism with or without marked bony deformities The blood proteins may fall low enough to cause a moderate edema

Stools —Steatorrhea is characteristic of sprue but not pathognomonic of this disease In the normal stool not more than 15 per cent of the dry weight is fat whereas

has become irreversible and even maximum therapy will yield poor results The liver therapy must be *adequate* to control the symptoms regardless of the amount and the parenteral route is the method of choice Liver therapy must be more intensive in sprue than in pernicious anemia for although the blood responds readily to treatment the gastro intestinal tract is much slower in returning to normal In long standing cases of sprue especially in the aged the tendency to recurrence of steatorrhea may persist for years Such patients will require maintenance doses of liver to control the diarrhea even when the blood has been restored to normal

Since sprue patients assimilate fats poorly these should be restricted at first to 25 or 50 Gm daily and only gradually increased with cessation of diarrhea In some patients because of meteorism carbohydrates must be reduced Ripe bananas and banana flour are well tolerated Under the influence of adequate liver therapy the glossitis quickly heals the papillae regenerating with astonishing rapidity and the appetite improves so promptly and remarkably that the feeding of a full generous diet usually is possible at once A high protein high vitamin diet is recommended and this alone may control the early or mild cases Brewers yeast or autolyzed yeast (vegex marmite) 1 teaspoonful in a glass of warm water after each meal has proved useful but may cause distressing meteorism

As the blood count rises the color index falls and iron should be given early in full doses Calcium lactate and phosphate (of each 2 Gm 30 grains) should be given daily and if evidence of deficient calcification is present vitamin D (viosterol, percomorph oil) should be added

sprue macrocytic hyperchromic anemia is very rare though it does occur The bone marrow in childhood seldom reacts to injuries in a macrocytic hyperchromic manner, and therefore pernicious anemia is very rare in children

Gastric Analysis —Achlorhydria after histamine stimulation (0.5 mg) does not occur in sprue more frequently than in normal individuals Hypochlorhydria is the rule but as the patient improves under proper treatment the free HCl increases and if it has been absent it may return Of 50 cases of sprue observed in Duke Hospital by the writer 21 per cent showed an absence of free HCl in the gastric juice after histamine stimulation Ogilvie found that two of fifteen patients (13 per cent) with celiac disease had achlorhydria after histamine stimulation

The differential diagnosis of sprue in its earlier stages may be difficult If however the clinical features of the disease are borne in mind a careful history elicited with especial reference to nutritional deficiencies and if the blood stools and blood sugar curve are thoroughly studied evidence pointing to the deficiency state called sprue will be uncovered *Great loss of weight steatorrhea a low blood sugar curve and megalocytic hyperchromic anemia are four findings characteristic of sprue*

Pernicious anemia frequently has been confused with sprue because of the glossitis and macrocytic hyperchromic anemia common to both These are really their only essential points of resemblance Achlorhydria after histamine stimulation is a constant finding in pernicious anemia the blood sugar curve is not low, diarrhea may occur but is not fatty and the progressive emaciation so characteristic of sprue is not a part of the clinical picture of pernicious anemia The two syndromes present more differences than similarities and by using modern methods of study there should be no excuse for confusing them It is not improbable that the reported cases of pernicious anemia with free HCl in the gastric juice were in reality instances of the sprue syndrome The differentiation of pernicious anemia from sprue is of the utmost importance for in pernicious anemia the patient is condemned to a lifetime of troublesome and expensive therapy whereas in the light of present knowledge it is believed that sprue is as a rule curable provided that the underlying dietary deficiency is permanently corrected

Pellagra and Addison s disease bear only a superficial resemblance to sprue and should cause no real diagnostic difficulties Pancreatogenous steatorrhea unlike the diarrhea of sprue is characterized by great loss of nitrogen in the feces (azotorrhea) which can be demonstrated microscopically in the form of undigested striated muscle fibers, and the blood sugar curve is diabetic in type

Tabes mesenterica may cause steatorrhea, but the blood sugar curve is not low the anemia is hypochromic and the finding of tuberculosis elsewhere in the body clarifies the diagnosis

Steatorrhea and azotorrhea may follow fistulous connections between the stomach and intestines and for understandable reasons an addisonian like anemia may thus be produced Such cases studied with the aid of x rays will not offer any serious difficulties in diagnosis

Prognosis —Sprue unlike pernicious anemia is a curable disease in the large majority of sufferers but if treatment is too long delayed unsatisfactory results and even failures may occur There would seem to be a stage in the natural history of the disease from which complete recovery is impossible with our present therapy On the other hand even the most advanced cases often respond in a satisfactory manner

Treatment —Until recently sprue was treated with a great variety of special diets which are now of only historic interest In 1927 Bloomfield and Wyckoff applied to a case of sprue with macrocytic hyperchromic anemia the liver treatment which Minot and Murphy had just shown to be efficacious in pernicious anemia They observed prompt improvement featured by rapid cessation of diarrhea a remarkable gain in weight and improvement of strength and well being The reticulocytes increased the blood count rose and finally a normal blood picture was established This has been the experience of many subsequent observers When treatment is begun early the response is brilliant but in a certain number of far advanced and long neglected patients the disease process

must be included in protective diets' like those of McCollum to prevent wastage of stored body protein The deposit" protein in the body as shown by Boothby constitutes a large reserve but varies considerably in extent with thyroid activity and is depleted in protein deficiency When adequate caloric intake is assured the minimal daily requirement of protein may be as low as 0 6 Gm per kilo but ordinarily one hopes for twice this amount including a goodly assortment of amino acids For growth and pregnancy a greater factor of safety is needed else large amounts of body protein may be destroyed to procure enough of a single amino acid The injection of peptone may produce 'pep tone shock in which extensive lysis of pro tein occurs In hyperthyroidism or fever increased assimilation of fat and carbo hydrate may spare protein but it is unde cided how infectious toxins act *per se*

When the intake of unsaturated fatty acids is too low Burr and Burr found that disease results Likewise when carbohydrate contributes less than 10 per cent of the total caloric intake increased azoturia and keto nuria occur in many individuals

oxidized normally A similar explanation may be given for cystinuria and pentosuria

In other instances the destruction of a particular organ may be the cause, as in the accumulation of amino acids in hepatic atrophy Less well understood is the accumu lation of liver glycogen in von Gierke s dis ease

Homeostatic Equilibria in Clinical Chemistry—The constancy of the *milieu interne* emphasized by Claude Bernard was studied by L J Henderson in physicochemi cal terms The acidity of the body fluids is maintained nearly constant locally by buffer systems Despite the acidic trend of human catabolism the kidney preserves neutrality by excreting acid phosphate for basic phos phate and by substituting ammonia for sodium With the rise of systematic clinical chemistry under the schools of Folin and D D van Slyke many other steady states have been disclosed Thus electrolyte patterns of the plasma in health and disease have been compiled by Gamble expressed in milli equivalents per liter so that ions of various atomic weights may be summated in com mon units A typical normal distribution is

Total base = total acid

Sum of cations (positively charged ions) = sum of anions (negatively charged ions)

Na	+ K	+ 2 Ca^{++}	+ 2 Mg^{++}	= Cl	+ HCO	+ f × protein	+ H_2PO	+ R †	
Expressed as milliequiv per liter									
142	+ 5	+ 5	+ 2	= 105	+ 25	+ 17	+ 2	+ 5	= 154
Expressed as vols per cent					48				
Expressed as mg per 100 cc									
327	+ 19	+ 10	+ 2 4	3,4		f × 7000	+ 3 1		

The net capacity of the combined plasma proteins to bind base at *p*H 7 4 is calculated by multiplying the factor *f* times the protein concentration

† Organic acid radicles plus sulfate

Intermediary Metabolism—In certain metabolic diseases the normal fate of a met abolite is blocked by failure of some cellular mechanism Thus Garrod in 1848 recog nized that in podagra uric acid accumulated in body fluids Likewise the acetone bodies of diabetic coma are natural intermediates whose normal pathway has become con gested because of excessively rapid fat cat abolism In thiamine deficiency pyruvic acid accumulates because natural mechanisms concerned with oxidation have failed In the xanthomatoses the reticulo endothelial sys tem is overloaded with lipoid the normal disposition of which has failed In the mental defectiveness studied by Folling phenyl pyruvic acid is excreted instead of being

When calcium rises phosphate tends to fall and vice versa Likewise in Addison s hypoadrenocorticism a fall in sodium usu ally is accompanied by a rise in potassium The total osmotic pressure can vary only within narrow limits and the sum of the cations must equal approximately the sum of the anions with due regard to the protein present Because the total base varies but little changes in the chloride and bicarbo nate ions tend to be reciprocal The intra cellular tissue fluids constitute a reservoir of body water and electrolyte from which losses from blood or cells may be replaced as shown by Peters

Most steady states depend upon some regulating action of the central nervous

DISEASES OF METABOLISM

INTRODUCTION

Energy Requirements in Health and Disease—Lavoisier measured the oxygen consumption of resting man and demonstrated that higher values were found during digestion during exercise and exposure to cold Subsequently Pettenkofer and Carl Voit applied the heats of combustion of the three principal foodstuffs to indirect calorimetry applicable to patients They found that the amount of oxygen required for metabolism depends upon the composition of the mixed foodstuffs being burned as judged by the respiratory quotient Voit showed also that the intensity of the caloric turnover regulated the amount of oxygen assimilated, but that even hard exercise did not increase protein catabolism Much later Atwater and Rosa with their large calorimeter demonstrated with nicety that the first law of thermodynamics applies to man

Rubner's finding that the caloric equivalent of the resting individual's metabolism is proportional to his surface area led to the formulation of standard tables for men and women by Harris and Benedict and by Aub and Dubois Plummer and Boothby introduced the term basal metabolic rate (B M R) to indicate in terms of surface area the relative intensity of bodily combustion at rest and in the relaxed fasting state The normal value is relatively high for infants rises again at puberty and declines gradually with advancing years Women show lower values than men but the basal caloric requirement for normal adults is approximately 25 calories per kilogram daily or 40 calories per square meter per hour Fever increases this value on the average by 7.2 per cent for each Fahrenheit degree of elevation It falls with inanition myxedema and lipoid nephrosis and rises with leukemia and hyperthyroidism

Obviously exercise increases the total daily caloric consumption far above the basal level so that a tailor might require only 2300 calories daily a carpenter 3300 and a lumberman 5000 It should be noted that medical usage has corrupted the kilogram calorie or Calorie to "calorie"

The Fundamental Foodstuffs—By 1840 Liebig had accepted the principle of nitrogen equilibrium in health and the concept of a maintenance ration On multiplying fecal and urinary nitrogen excretions by 6.25 protein metabolism could be estimated approximately and the nonprotein respiratory quotient used to measure the proportion of fat and carbohydrate being burned When carbohydrate is burned the volume of carbon dioxide produced per volume of oxygen consumed gives a ratio of 1 0, whereas the respiratory quotients for average protein and average fat are 0 78 and 0 71, respectively In fasting the R Q may fall to 0 69

Rubner's standard values for the energy values of the primary foodstuffs in kilogram calories per gram were 4 1 for protein 4 1 for carbohydrates, and 9.3 for fat The latter two values have been verified by combustion in the calorimetric bomb but one fourth of the energy of combustion of meat protein is lost to the animal Rubner also found that the specific dynamic action of ingested foodstuffs maximal after three hours, was 30 per cent for protein 6 per cent for carbohydrate and 4 per cent for fat The actual cause of this dietary increase in resting metabolism remains unknown Rubner's 'iso dynamic' principle stated that within certain limits 100 grams of fat could be removed from a balanced diet and replaced by 232 Gm starch 234 Gm cane sugar or 243 Gm dried meat Of course this principle is limited by certain other requisites a minimal demand for essential amino acids a minimal need for carbohydrate to spare protein and to prevent an undue demand upon fatty acid catabolism, and adequate supplies of accessory foodstuffs such as vitamins and minerals

By 1915 Osborne and Mendel had demonstrated the requirement of certain definite amino acids as building stones for body structure These include tryptophane histidine cystine and lysine (for growth), which

tends to mobilize these reserves Thus the effects of various hormones are mutually poised against the others The anterior pituitary provides a super-regulation through its several tropic hormones each specific for a peripheral endocrine organ When the thyroid or gonad is removed there is an increase in the circulating specific tropic hormone—the so-called "castration effect

By such reciprocal interplay of the pituitary thyroid axis" a steady rate of tissue combustion is achieved So nice is this balance that the microdetermination of protein bound iodine in the plasma may be used to measure net thyroid activity Thus in myxedema the value may be nearly nil in euthyroidism 5 to 7 micrograms per cent and in "thyroid storm 18 micrograms per cent

Measurement of plasma enzymes is occasionally useful The alkaline phosphate was utilized by Kay to study bone disease especially in disturbances of parathyroid function The acid phosphatase of the Gutmans reflects metastasizing prostatic cancer In acute pancreatic necrosis a sharp rise in serum amylase occurs

The concentration of hormones and enzymes in body fluids is much lower than that of metabolites like sugar or urea The former are expressed in *micro*grams per cent whereas the latter are stated in *milli*grams per cent. This thousand fold difference in concentration reflects the distinction between catalyst and substrate

GOUT AND GOUTY ARTHRITIS

Definition —Gout is a disease of unknown origin characterized chiefly by (1) acute paroxysmal arthritis which is followed by complete remissions but which tends to recur later the arthritis may become chronic (2) a supposed abnormality in the renal excretion of uric acid the end product of purine metabolism this disturbance is also somewhat cyclic and varies in intensity (3) hyperuricemia, usually transient at first, later chronic (4) deposits of sodium urate crystals in articular periarticular and subcutaneous tissues sometimes also in kidneys these deposits generally appear in the later less commonly in the earlier phases of the disease (5) frequent terminal lesions in kidneys sometimes also in the vascular system of heart and brain

Etiology —Certain older hypotheses have been discarded or remain unproved. These were that gout resulted from (1) primary renal insufficiency causing retention and deposition of urates with resulting acute inflammation (2) disturbed blood alkalinity causing precipitation of urates (3) disturbance of the central nervous system (4) some hepatic dysfunction or (5) infection producing secondary metabolic abnormalities

Gout is commonly defined as a disturbance of purine metabolism The accompanying hyperuricemia has been considered the result of (1) excess formation (2) deficient excretion or (3) diminished destruction of urates in the body The idea of overproduction of urates seems untenable since no increased excretion or accumulation of phosphates accompanies the hyperuricemia as would be expected if destruction of nuclear protein were increased Investigators frequently have noted subnormal amounts of urates in the urine of gouty persons but this is not consistent or persistent Indeed some gouty patients both during and between acute attacks excrete more urates than nongouty controls (Talbott and Coombs) It has been suggested that gouty

system, but many such equilibria are largely kinetic rather than thermodynamic This "wisdom of the body" (Cannon) is frequently mediated through hormones It may be masked temporarily by digestion and absorption of food or by severe exertion or disease Tolerance tests are applied to try the inherent stability of such mechanisms under known strain Sometimes a deviation from the natural equilibrium serves a useful purpose Thus with the loss of electrolyte in high intestinal obstruction accumulating urea tends to compensate osmotically for loss of inorganic constituents

The existence of "renal thresholds" for glucose, calcium chloride and phosphate also serves to maintain homeostasis Thus a fall in serum chloride to 100 mEq/L or of calcium to 5 mg per cent, causes these substances to disappear from the urine Conversely at about 170 mg per cent glucose is excreted

The existence of these equilibria forms the chief basis for modern clinical blood chemistry Peters and Van Slyke have discussed them in detail The most useful procedure is to study equilibrium after overnight fasting but time curves following the administration of known material may be used to test metabolic tolerance The three principal classes of foodstuff are frequently examined in this way

Thus normal values for plasma protein usually range from 6.5 to 7.5 Gm per cent whereas for incipient edema the critical average values are 5 0 to 5.5 for total protein and 2.5 for albumin The blood urea nitrogen or the plasma nonprotein nitrogen reflects both the course of protein metabolism and the renal efficiency in clearing the organism of such waste products For the former normal values are usually between 9 and 14 mg per cent for the latter between 25 and 35 mg per cent Obviously low values may be found in inanition and after diuresis High values occur in dehydration heart failure and nephritis when excretion is poor or when protein breakdown is excessive as after severe burns Under special circumstances specific nitrogenous catabolites may be examined Thus the serum uric acid lies between 3 0 and 5 0 mg per cent and repeated fasting values above 6 0 suggest gout The blood creatinine normally ranging from 1 0 to 1.8 mg per cent, becomes elevated when renal clearance is poor Accordingly, in nephritis the prognosis is poor at 10 mg per cent and exitus is imminent at 18 mg per cent

Carbohydrate metabolism is reflected by the plasma glucose concentration normally about 70 to 100 mg per cent Many factors influence its magnitude particularly endocrine balance Likewise low values may occur in exhaustion or hepatic necrosis because liver glycogen reserves are low High values usually indicate sympathetic activity in the absence of diabetes mellitus Albright has used the glucose-insulin tolerance test to gauge the reserve of various endocrines especially the adrenal cortex, as an aid to diagnosis

Of the circulating lipoids blood cholesterol has been used most extensively In many laboratories normal values range from 140 to 170 mg per cent In hyperthyroidism the level tends to be low High values are found in pregnancy myxedema and in the "nephrotic syndrome" In liver disease also high readings may occur

The Regulators of Metabolism—Health is maintained by certain catalysts which are called hormones vitamins and enzymes Probably the hormones circulate about the body to regulate appropriate enzyme systems in individual cells Thus a single hormone may produce opposite effects in different tissues The vitamins may constitute specific key groups in such enzyme systems The central nervous system too is involved in neurohumoral mechanisms which control vital equilibria Thus C N H Long has demonstrated that diencephalic lesions cause excessive food intake with resulting formation of fat and so lead to obesity Likewise the neurohumoral action of sympathetic and parasympathetic nerves results in the liberation of sympathin E or I or of acetylcholine

Some hormones exert anabolic effects, others catabolic For example the adrenal medulla liberates epinephrine which causes the rapid liberation of energy stores Testosterone on the contrary favors the storage of protein thus increasing muscular development and growth of body hair Insulin exerts a conservative action which replaces stores of protein and glycogen despite the antagonism of the thyroid hormone which

even bony ankylosis sometimes ensues (Ludwig Bennett and Bauer)

Urates may be deposited as white dots or streaks in renal substance or as orange-colored gravel or calculi in renal calices Foreign body reactions occur about the interstitial urate deposits these with the lesions of arteriolar nephrosclerosis and some glomerular fibrosis constitute the tissue reactions of gouty nephritis

Pathogenesis —In considering the pathogenesis of gout one must separate it into its components and study their interrelationships The agent or agents which cause the gouty state the acute gouty arthritis and the vascular complications are unknown Urate deposits may well be the chief cause of gouty nephritis and of chronic gouty arthritis When articular tissues can no longer cope with the reactions to urates chronic gouty arthritis develops Disturbances of uric acid are now considered the result not the cause of the disease Recent studies indicate that in gout cyclic variations in the excretion of several salts besides urates occur (Talbott Jacobson and Oberg) Hyperuricemia or urate deposits likewise are not considered the cause of acute attacks because marked hyperuricemia accompanies other diseases (*e g* leukemia) without commonly invoking gouty arthritis There is no consistent relationship between acute attacks and formation of tophi or the degree of hyperuricemia acute attacks are relieved by colchicine which has no known effect on the urinary or on the total blood uric acid (But it may lower the bound uric acid in serum)

Symptoms.—*Classic Gout.*—The chief features of gout (the arthritis hyperuricemia tophi and late renal and cardiovascular complications) are only the outward signs of some fundamental chemical or metabolic disturbance of which little is known This disturbance called 'gout per se' or gouty diathesis is probably symptomless for some time before acute arthritis first appears and under suitable provocation causes the subsequent appearance of the classic symptoms During the larval stage of gout the body is being unobtrusively conditioned for subsequent events but what chemical or histologic abnormalities are then transpiring is unknown

Evolution of the Continuing Pattern of Gouty Arthritis —Gout and gouty arthritis are not synonymous the latter is merely the dominant symptom of gout Gout can best be studied by noting the relationship of its other features to the pattern of gouty arthritis (Fig 54) The first attack of acute gouty arthritis usually occurs suddenly lasts about three to ten days and then disappears completely It affects a great toe or with almost equal frequency an instep ankle knee or other region The typical acute attack often comes on at night The pain which is at first moderate increases in intensity In severe attacks the pain is so intense that even the weight of the bed clothes and the vibration of the bed add to the patient s distress Toward morning the pain abates and the patient may fall asleep On examination the affected joint is swollen and exquisitely tender The skin is of a deep red color sometimes almost purplish and

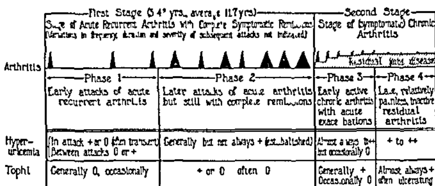

Fig 54 —The basic pattern of gout and gouty arthritis (untreated) (Hench P S J Lab and Clin Med Oct., 1936)

patients are deficient in some purinolytic ferment, hence do not destroy urates adequately, but others insist that man does not possess the property of uricolysis, still others have believed that gouty patients destroy unusual amounts of urates, hence excrete subnormal amounts Whether or not gout is to be considered a disturbance of purine metabolism depends on the definition of such disturbance Gouty persons apparently catabolize foods through the same successive steps from purine bodies to uric acid as do normal persons, hence there is no obvious abnormality of intermediary purine metabolism Thus gout is not truly a disturbance of purine metabolism even though it involves a faulty disposition of urates

Newer opinions are that gout results from (1) some endocrine deficiency, (2) abnormal renal insensitivity to urates (3) selective renal insufficiency for urates alone (4) a "storm in the vegetative nervous system" a functional disturbance involving thoracic (Tinck) or renal (Grabfield) sympathetics or (5) an allergic reaction to proteins not necessarily to exogenous proteins derived from foods rich in purine, but also to proteins from nonpurine foods as well as to endogenous proteins tissue substances formed after injuries vasomotor disturbances or surgical operations

Incidence of Factors Governing Gout—Contrary to the belief of many physicians gout has not disappeared it is seen with increasing frequency by those looking for it At the Mayo Clinic patients with classic gout constitute at least 5 per cent of those seen by consultants on diseases of joints Reported statistics on the incidence of gout often give an inaccurate idea of the situation because the diagnostic criteria of various physicians differ materially Gout is recognized in private practice much oftener than in general hospitals

Several predisposing factors govern the incidence of the disease

Sex—Classic gout may affect females but about 95 per cent of patients are males If a writer states that many more than 5 per cent of his gouty patients are females his diagnostic criteria are open to question An interesting case of gout and male hermaphrodism has been reported recently (Rosenberg)

Age—Symptoms first appear generally among persons aged thirty five years or more occasionally among persons aged sixty or seventy years and rarely among children in their teens When juvenile gout occurs the hereditary factor is more apparent and the progress of the disease is more rapid than when it first affects adults

Heredity—Familial gout affected 22 to 81 per cent of patients in five English series but only 7 to 12 per cent in five America series More thorough inquiry might raise the latter percentages

Race and Climate—Gout occurs mostly in temperate zones It is common in England and France less common but increasing in North America Hebrews often are affected prosperous American Negroes occasionally

Food and Drink—This is discussed later

Occupation—Commonly affected are those in occupations favored by the well to-do (lawyers clergy, physicians) or those which permit gastronomic indulgence (inn keepers brewers)

Morbid Anatomy—The specific histologic features of gout are best demonstrated by the Galantha method which utilizes absolute alcohol as a fixative and silver nitrate to stain the urates Specific lesions consist of urate deposits in articular periarticular, and sometimes in renal tissues It is not known when during the course of the disease these deposits occur They have been found as early as a couple of days after the inception of the first acute attack' (Brøchner Mortensen) Articular changes depend on the amount of such deposits their location and the resulting reaction to them They are found in cartilage, synovial membrane perichondrium subchondral bone and bone marrow periosteum the fibrous capsule adjacent ligaments tendons and bursae especially of the olecranon The deposits invoke a foreign body cellular reaction with proliferation of fibrous tissue Cartilaginous degeneration and secondary proliferation of marginal bone (secondary hypertrophic arthritis) may occur, as well as bony destruction (destructive arthritis) Areas of erosion, osseous tophi in subchondral and marginal bone generally appear in time as the result of replacement of bone by urates Synovial pannus formation eventually may invade cartilage to the extent that fibrous or

condition perhaps at their normal expectancy

Irregular Gout—Diagnoses of irregular (as opposed to classic) articular gout are still made by some physicians when arthritis begins insidiously and progresses chronically without complete remissions or tophaceous deposits simply because of supposed familial gout or because of the presence of hyperuricemia (not necessarily gouty) Since provable or tophaceous gout practically never develops that way the evidence supporting irregular articular gout is unconvincing Likewise most diagnoses of visceral or abarticular gout cannot be supported because symptoms are indistinguishable from those of nongouty patients of similar age are not consistently or even commonly present in cases of proved (tophaceous) gout and are not consistently relieved by a gout regimen

Complications of Gout.—The only valid examples of visceral gout are found in the cardiovascular renal system Degenerative vascular disease may complicate late gout and cause death by coronary or cerebral vascular accidents The vascular lesions are nonspecific and contain no tophi but intracardiac tophi have been seen Gouty nephritis and renal colic from urate gravel or stones accompany the second stage of gout in from 10 to 30 per cent of cases and the first stage occasionally Hence suspect gout in cases of acute or chronic arthritis with

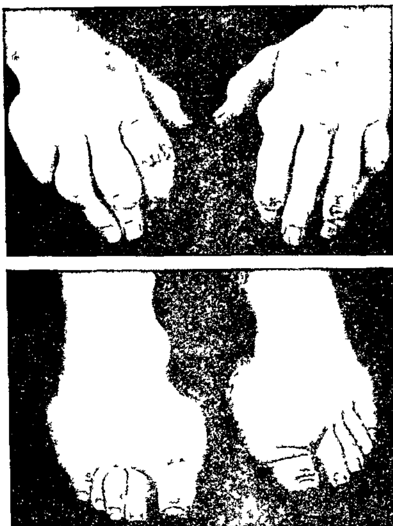

Fig 56—Severe chronic gouty arthritis with ulcerating tophi.

the veins are distended As the swelling subsides the cuticle peels and there is often local itching Another attack perhaps more severe or longer occurs in about a year or perhaps not so soon, it also disappears completely (Fig 55) Sooner or later the disease generally increases in tempo and severity, attacks come semiannually or more often Early attacks are generally monarticular and afebrile, later attacks are often polyarticular and may be febrile (temperature of 102° F or more) Certain roentgenologic changes may appear after several acute attacks and may remain but despite these in this stage of the disease joints recover full symptomless function

shapen subcutaneous tophi are found at various points on the extremities as well as on the ears (Fig 56) Swelling of the olecranon and prepatellar bursae is common The walls of the bursae become thickened and their sacs contain sodium urate In severe cases, there may be marked crippling because of the involvement of many joints

Thus the pattern of classic gouty arthritis can be divided into two great stages comprising four phases (Fig 54) Stage 1 is that of acute recurrent gouty arthritis and stage 2, of chronic gouty arthritis Phase 1 of stage 1 is that of the early, less severe and generally more localized attacks Hyperuricemia may be absent or if present is mild

Fig 55—Acute gouty arthritis of great toe

From five to forty (average twelve) years after the first attack an important change occurs joints no longer recover completely some stiffness pain or deformity remains Thus begins the second stage of articular gout that of *chronic gouty arthritis* The chronically affected joints at first are subject to superimposed acute attacks with incomplete remissions finally exacerbations largely cease and the joints take on the character of the chronic disease In contrast to acute gouty arthritis which is usually monarticular chronic gouty arthritis is nearly always polyarticular the joints of the hands and feet are swollen and mis

or poorly established Phase 2 comprises the later generally more severe and longer attacks which are often polyarticular and associated with more definite and persistent hyperuricemia but are still followed by complete symptomatic remissions Phase 3 (phase 1 of stage 2) is that of early chronic gouty arthritis with acute attacks and incomplete remissions phase 4 (phase 2 of stage 2) is the final relatively painless chronic gouty arthritis Young patients who have active gout may reach stage 2 in middle life Patients who develop gouty arthritis in middle or late life frequently never reach stage 2 but may die of some unrelated

of gout is made only after demonstration of tophi many cases are missed and valuable time is lost

OSSEOUS TOPHI (EROSIONS) —Areas of erosion of articular bone *in gout* represent osseous tophi or replacement of bone by urates (Fig 59) Such tophi are not uncommon in phase 1, fairly common in phase 2 increasingly numerous and large in phases 3 and 4 Areas of erosion caused by replacement of bone by nonuratic debris often occur in rheumatoid or in osteoarthritis and in lupus pernio Hence areas of erosion are not pathognomonic for gout but if they are

Fig 58—Urate crystals from gouty tophus (× 435)

large or numerous they are usually due to gout

Diagnosis in Absence of Characteristic Features—The presence of any characteristic feature (podagra hyperuricemia tophi or erosions) is of great diagnostic import but their appearance is often delayed until rather late in the disease Features more reliable for early diagnosis are the characteristics of the individual attacks and especially the obvious evolution of the clinical pattern of gouty arthritis This pattern (acute recurring attacks complete remissions) is so distinctive as to be almost pathognomonic and permits a diagnosis of presumptive (pretophaceous) gout with no little assurance since it is not exactly mimicked by the other articular diseases which have recurrences and remissions (*e g* rheumatic fever and intermittent hydrarthrosis) When the patient is seen in the first attack with only a fragment of the pattern in view diagnosis is based on certain features of the single attack, no one feature alone is diagnostic but a combination of features is almost pathognomonic of gout

Individual Attacks of Gouty Arthritis Diagnostic Features—PREDISPOSING FACTORS—SEX AND AGE—Among males over

Fig 59—Area of erosion (tophus) distal end of proximal phalanx of great toe

thirty five or forty years of age acute gouty arthritis is the most common form of acute arthritis and should be suspected if gonorrhea and acute trauma are excluded

SEASON—Attacks occur any time but commonly in the spring and fall

OTHER PREDISPOSING FACTORS—These are heredity habitual excesses in food and drink and blood dyscrasias (polycythemia leukemia) involving destruction of blood and liberation of nucleoproteins

PRECIPITATING FACTORS—Common provocatives of gouty arthritis are trauma and dietary indiscretions less common are infections surgical operations certain medicines and psychic upsets Patients rarely

renal colic or nephritis" Very rarely patients may pass urate gravel before the first attack of gouty arthritis

Ulcerating tophi often complicate late gout and may lead to amputation of digits for supposed felons

Diagnosis—Podagra (painful great toe) hyperuricemia subcutaneous tophi and osseous tophi (erosions in roentgenograms) generally are considered of greatest diagnostic value It is commonly believed that the great toe is attacked almost exclusively that hyperuricemia appears early and persists that only a short time elapses between toe and tophus and that evidence of

Fig 57—Two tophi on ear

osseous tophi appears early in roentgenograms These conceptions are largely incorrect

Frequency and Diagnostic Value of Podagra—The metatarsophalangeal joint of a great toe is involved in only about 60 to 70 per cent of initial attacks In some cases it is affected repeatedly in others rarely or never One must not refuse to diagnose gout because podagra is absent

Relation of Hyperuricemia to the Pattern of Gouty Arthritis—The evolution of hyperuricemia frequently *but not necessarily* parallels that of arthritis In the larval or pre arthritic stage symptomless and generally transient hyperuricemia may or may not develop, on rare occasions subcutaneous tophi or urate gravel accompanies it even in this stage Certain Boston students of gout have stated that once arthritis occurs hyperuricemia is present and persistent My experience and that of others contradicts this view In phase 1 of gouty arthritis (Fig 54) hyperuricemia is often present but is frequently absent not only between but during acute attacks In later attacks (phase 2) it becomes more frequent more notable and more persistent In phases 3 and 4 (stage 2) it is almost always present in untreated patients, but under proper treatment it often disappears temporarily The level of blood uric acid does not determine the severity of the arthritis and untreated cases of tophaceous gout occasionally exhibit no hyperuricemia, the normal value for uric acid in the blood is 2 to 4.5 mg per 100 cc (Folin 1930) In summary hyperuricemia is usually present but one must not insist on its presence before diagnosing gout

Evolution and Frequency of Tophi—VISIBLE OR PALPABLE SUBCUTANEOUS TOPHI—These may develop at any stage They are very rare in the pre arthritic stage rare in phase 1 fairly frequent in phase 2 almost always present in phases 3 and 4 when they may be multiple and ulcerating They occur most frequently on ears (Fig 57) and about olecranon bursae and after several attacks they may appear about peripheral joints When tophi are present a diagnosis of tophaceous gout with acute recurrent or chronic gouty arthritis is made when tophi are absent, a diagnosis of presumptive (pre-tophaceous) gout is made on the basis of data to be described later A tophus is not a proved tophus until it has been opened and urate crystals found (Fig 58) Sometimes its identity should be certified further by the murexide test or histologic study

Tophi are found in only about 40 to 50 per cent of all cases They occur more often than this in late or more severe cases less often in early or mild cases The incidence of tophi reported by any physician gives a clue to the accuracy of his diagnostic criteria he is probably too exclusive in diagnosis if tophi are present in 65 per cent or more cases not exclusive enough if they are present in 25 per cent or less But if a diagnosis

useful the administration for a few days of excessive quantities of purines (2.3 Gm daily) and fats perhaps also of alcohol liver extract and ergotamine tartrate Such tests are of limited value As articular vulner ability appears to vary notably from time to time a definite attack may or may not result

Therapeutic tests are more impressive If a stubborn attack promptly responds to colchicine and restrictions of purines and if the disease subsequently is largely or com pletely controlled by a gout regimen, the skeptic will be convinced even without the presence of hyperuricemia or tophi

Roentgenograms—Development of the specific roentgenographic features (erosions or osseous tophi) is governed by the gradient of articular vulnerability and by the number and severity of attacks in any given joint Even in severe gout areas of erosion rarely occur except in feet and hands They appear occasionally in phase 1 commonly in phase 2 and thereafter Periarticular thickening and hypertrophic and destructive changes nonspecific in type may involve affected joints sometimes in phase 1 but generally not until phase 2 and thereafter Roentgeno grams are of limited usefulness in diagnosis characteristic changes are seen rarely in the early generally not until the later phases of gout

Laboratory Data—As stated hyper uricemia is usually present sooner or later but may be absent early in the disease Estimations are generally made on whole blood Jacobson stated that tests made on serum collected under oil were more accu rate serum contains a little more uric acid than whole blood The old argument as to the presence of free and bound uric acid in blood has been reopened by Adlers berg Grishman and Sobotka who studied the uric acid partition of serum by means of ultrafiltration In cases of gout (and also of hepatic damage in nongouty persons) there occurred disturbances of the uric acid partition characterized by a diminution of the free (ultrafiltrable) and an elevation of the bound (nonultrafiltrable) uric acid frac tion in serum Even in certain cases of gout in which the total serum uric acid was nor mal the values for bound uric acid were abnormally high Sedimentation rates may be normal in mild attacks elevated in severe acute attacks and in chronic gouty arthritis Sedimentation rates and values for blood uric acid apparently reflect unrelated factors Hypercholesterolemia may be present Arneth counts may show a left shift

Treatment —The most important point in the treatment of gout is its recognition this done few articular diseases will respond more promptly

Prophylaxis—Children of gouty parents sometimes demonstrate symptomless hyper uricemia such hereditary candidates should live moderately and avoid or undertake cautiously the various provocatives of acute gout as well as occupations conducive to gastronomic overindulgence

Treatment of Acute Gouty Arthritis—Patients who experience monarticular pro dromata or warning articular twinges can sometimes abort attacks by taking a brisk cathartic and from five to ten doses of col chicine ($\frac{1}{100}$ grain or 0 65 mg every two to three hours) The additional use of sodium salicylate (25 grains or 1 6 Gm three times daily) or cinchophen ($7\frac{1}{2}$ grains or 0 48 Gm three times daily) for a few days may be helpful by combating hyperuricemia Patients are wiser to accept such a regimen for a possibly false alarm rather than permit an attack to become established When an attack is established treatment includes the following measures

CATHARTICS—A brisk cathartic (mag nesium sulfate $\frac{1}{2}$ to 1 ounce [15 to 30 Gm] liquor magnesium citrate 6 to 12 ounces [180 to 360 cc] or sodium phosphate 4 to 8 Gm) is supposed to evacuate promptly provocative toxins although empiric its use seems helpful

REST—Affected parts should be com pletely rested preferably in bed and pro tected from bedclothes by a light wooden or metal cradle Weight bearing and activity should not be resumed until pain and tender ness are gone, otherwise an exacerbation may result

HEAT OR COLD—Simple hot water com presses applied every two or three hours are generally effective and often preferable to dry heat compresses of magnesium sul fate or lead lotion are sometimes prescribed Occasionally cold compresses give the most relief

mention them, they must be sought Attacks may be precipitated by such minor trauma as that from a walk of unaccustomed length that incident to excessive sight seeing or to long motoring (pedalling) or that from excesses in golf or amateur labor (lawn mowing) True traumatic arthritis begins immediately after trauma, the inflammatory reaction is in proportion to the severity of trauma is confined to the traumatized region and is not relieved by colchicine the characteristics of gout (history hyperuricemia, tophi) are absent In posttraumatic gouty arthritis the inflammatory reaction is often delayed some hours after trauma is out of proportion to the trivial trauma often progresses to other joints and is relieved by colchicine other characteristics of gout may also be discoverable

Gouty arthritis is often provoked by dietary excesses associated with birthdays weddings, Thanksgiving New Year's Day Passover sales conferences conventions lodge-night Potent provocatives are hunting and fishing trips characterized by trauma and indiscretions around the camp fire (venison meats liquor) Gout however, may affect vegetarians and teetotalers Excesses of purines and alcohol do not cause gout any more than sugar causes diabetes but they may provoke quiescent gout and cause acute gouty arthritis so also may high fat and ketogenic diets used for therapeutic purposes Some attacks seem to be provoked by foods like asparagus not especially rich in purines

Medicinal provocatives include liver extracts although purine free salyrgan, ergotamine tartrate thiamine chloride (vitamin B_1), insulin (rarely) and decholin Lactic acid benzoic acid phenylacetic acid and similar compounds reduce the excretion of urates Transfusion purging and bleeding may provoke acute gouty arthritis When acute arthritis appears under these circumstances suspect gout

Patients with rheumatoid arthritis often feel temporarily better after any surgical operation Exacerbations of rheumatic fever occasionally develop in the second or third week after operation sometimes earlier Acute attacks of gout however, commonly develop within the first seven days after any surgical procedure

Prodromes —Most patients recognize no prodromes some note nausea, indigestion or dyspepsia, melancholia nocturia or polyuria irritability, vague muscular symptoms others experience euphoria and a ravenous appetite

Hour of Onset.—Attacks begin any time frequently in the early morning hours but usually are noted first when on awakening the patient puts foot to floor

Site of Onset —In gout there is a gradient of articular vulnerability whereby distal joints—feet ankles hands and wrists are most commonly affected Knees and elbows are less vulnerable, shoulders and hips are rarely affected except in severe or late gout the spine practically always escapes Olecranon bursitis and tendonitis especially of the Achilles tendon, often occur

Site of Maximal Tenderness —At the great toe maximal tenderness is usually on its medial aspect, not on its top or bottom as in rheumatoid arthritis

Appearance —An affected foot is more often warm and bluish red than clammy cold and bluish white is in rheumatoid arthritis Shiny skin some edema and as the attack recedes desquamation of skin often are notable

Progression of Attack —Attacks may develop slowly but generally develop rapidly maximal disability may appear within twelve to thirty six hours, this is a point of diagnostic significance

Pain —Pain may be mild or moderate but is often excruciating It is not always worse at night

Recovery —Recovery may be slow but is often (spontaneously) rapid occurring within a few days In stage 1 symptomatic articular recovery is complete despite certain roentgenographic residues A man severely crippled for days or even weeks shortly thereafter may recover completely as if never affected this point of diagnostic importance illustrates the comment of Aretaeus A persons subject to gout has won the race at the Olympic games during the interval of the disease

Diagnostic Value of Provocative and Therapeutic Tests —For the doubtful physician or the skeptical uncooperative patient the institution of a provocative test may be

TABULATION

Purine Content of Certain Foods*

List 1 Foods which contain very large amounts (150–1000 mg) of purine bodies in 100 Gm

Sweetbreads	825 mg	Kidneys (beef)	200 mg
Anchovies	363 mg	Brains	195 mg
Sardines (in oil)	295 mg	Meat extracts	160–400 mg
Liver (calf beef)	233 mg	Gravies	Variable

List 2 Foods which contains a larg amount (50–150 mg) of purine bodies in 100 Gm

Bacon beef calf tongue carp chicken soup codfish duck goose halibut lentils liver sausage meat soups partridge perch pheasant, pigeon pike plaice pork quail rabbit sheep shellfish squab trout turkey veal venison

List 3 Foods which contain a moderate amount (up to 50 mg) of purine bodies in 100 Gm

Asparagus bluefish bouillon cauliflower chicken crab eel finnan haddie ham herring kidney beans lima beans lobster mushrooms mutton navy beans oatmeal oysters peas salmon shad spinach tripe tuna fish whitefish

Also whole grain bread and breadstuffs graham bread graham crackers oatmeal crackers rye bread Rye Krisp whole wheat bread Zed

Also whole grain cereals Bemax bran bran flakes cracked wheat Embo graham porridge Grapenuts Krumbles malt breakfast food Pep bran flakes Pettijohns Puffed wheat Ralston's Sims Shredded Wheat Wheaties Wheat oats Wheat worth Whole Wheat Krumbles

List 4 Foods which contain an insignificant amount of purine or no purine

1 Beverages
- Carbonated
- Chocolate
- Cocoa
- Coffee
- Fruit juices
- Postum
- Tea

2 Butter

3 Breads and breadstuffs (except whole grain under list 3)
- Benson's water crackers
- Butter thins
- Corn bread
- Corn sticks
- French bread
- Gluten bread
- Holland rusk
- Soda crackers
- Uneeda biscuit
- Water rolls
- White bread
- Zwieback

4 Caviar

5 Cereals (except whole grain under list 3)
- Breakfast brownies
- Cornflakes
- Cream of wheat
- Farina
- Grits
- Post toasties
- Puffed rice
- Rice flakes
- Rice krispies
- White cornmeal
- Yellow cornmeal

6 Miscellaneous cereal products
- Arrowroot
- Hominy
- Macaroni
- Noodles
- Sago
- Spaghetti
- Tapioca
- Vermicelli

7 Cheese of all kinds

8 Eggs

9 Fats of all kinds (but eat in moderation)**

10 Fruits of all kinds

11 Gelatin

12 Milk
- Buttermilk
- Condensed milk
- Malted milk

13 Nuts of all kind
- Peanut butter

14 Pies (except mince meat)

15 Shad roe

16 Sugar and sweets

17 Vegetables
- Artichokes
- Beets
- Beet greens
- Broccoli
- Brussels sprouts
- Cabbage
- Carrots
- Celery
- Corn
- Cucumber
- Dandelion greens
- Egg plant
- Endive
- Kohlrabi
- Lettuce
- Okra
- Parsnips
- Potato
  - sweet
  - white
- Pumpkin
- Rutabagas
- Sauerkraut
- String beans
- Summer squash
- Swiss chard
- Tomato
- Turnips

18 Vegetable and cream soups (to be made with allowed vegetables and without meat stock)

19 Vitamin concentrates
- Cod liver oil
- Halibut oil
- Yeast

* To calculate the purines or purine bodies in a given food the purine nitrogen is multiplied by 3 example 200 mg of purine nitrogen equals 600 mg of purine bodies

** These foods are high in fat

COLCHICINE.—Colchicine tablets, each 1/120 or 1/100 grain (0.53 or 0.65 mg.), should be prescribed: 2 tablets initially and 1 tablet every two or three hours (in severe cases even during the night) until pain is relieved or gastro-intestinal symptoms (nausea, diarrhea) appear. Having once learned his toxic or "diarrhea dose" (which varies between 6 and 25 tablets, each 1/120 grain [0.00053 Gm.] but is usually about six to eighteen tablets), a patient in subsequent attacks may be able to obtain a satisfactory therapeutic effect without the toxic effect by taking 2 or 3 less tablets in a course. Colchicine is more consistently effective than the wine or tincture of colchicum (dose 15 to 30 minims every two to four hours) which sometimes deteriorates. Gouty patients should carry a few colchicine tablets for prompt use as necessary. It has recently been suggested that the beneficial effect of colchicine may be due to the fact that it lowers the bound rather than the total uric acid titer of blood serum.

NARCOTICS.—Until pain is relieved by colchicine and compresses the preliminary use of codeine (1/2 to 1 grain, 0.032 to 0.065 Gm.) or morphine sulfate (1/6 to 1/4 grain, 0.01 to 0.016 Gm.) may be required.

CINCHOPHEN.—Attacks are controlled better when cinchophen or a substitute for it is used to supplement other measures, especially if hyperuricemia is present; cinchophen should be given during attacks, thus: 7 1/2 grains (0.48 Gm.) three or four times daily with precautions noted hereafter (alkali, carbohydrates, extra fluid).

DIET.—The diet currently approved for acute gouty arthritis is one free of purines, low in fats (which inhibit urate excretion), rich in carbohydrates and in purine-free proteins (milk, eggs, cheese). This diet minimizes the formation of exogenous urates and fosters elimination of endogenous urates. Its rationale may be questioned when one realizes that many patients during attacks excrete urates normally or even excessively. Future work must determine how necessary purine restrictions are during attacks, but then of all times patients are receptive to instruction in those dietary restrictions which the interval treatment of gout seems to require. Complete avoidance of alcohol is advisable.

Interval Treatment of Symptomless Gout.—Gout is not cured when the attack is controlled. Gout is a chronic disease and treatment must be continued in an attempt to prevent or postpone return of symptoms. Contrary to the belief of some physicians that no regimen materially alters the course of gout, most physicians believe that, by adhering faithfully to the interval treatment, many patients can modify the course of the disease, reduce the number and severity of attacks, prevent or reduce the chances of chronic gouty arthritis and avoid or postpone the late and sometimes fatal complications. Thus thirty-one gouty patients who had suffered eighty-four major attacks before adhering to the interval treatment to be outlined thereafter experienced only seven minor attacks during a comparable period of years (Bartels).

CONTROL OF HYPERURICEMIA.—Despite its uncertain relationship to acute attacks, hyperuricemia undoubtedly is important in the production of chronic gouty arthritis, urate gravel and gouty nephritis, hence to combat it dietary restrictions and the intermittent use of urate eliminants should be continued.

DIETARY RESTRICTIONS.—Each patient must be treated individually as the stage and severity of his disease and his temperament dictate. In general the diet should be free of purines on two not necessarily consecutive days and low in purines five days a week. Normal diets contain 600 to 1000 mg. of purines daily; a low purine diet contains 100 to 150 mg. and can be attained roughly by allowing one food from list 2 (Tabulation) one day a week and one from list 3 four days a week, besides whatever foods are desired from list 4. Normal weight should be maintained and obesity avoided. Two days weekly the selections should be only from list 4. Foods in list 1 should always be avoided entirely; also spices, condiments, and rich or indigestible foods and sauces. Deficiencies in protein, iron and vitamin B_1 must be avoided; generally, the diet should be reinforced with an approved preparation of the vitamin B complex. At least 200 international units of thiamine chloride and 200 Sherman-Bourquin units of riboflavin should be given daily; also 5 grains of ferrous sulfate.

neously ascribed to cinchophen are produced by the alkali An alternate method of urinary alkalinization then is necessary

Additional Measures—Contrary to general opinion a few physicians consider colchicine preventative of acute attacks and prescribe $\frac{1}{120}$ grain (0 00053 Gm) three times daily for two or three days each week or for one week each month With similar intent Vorhaus and Kramer gave vitamin B_1 (thiamine chloride 330 to 3300 international units) daily, even though initial doses commonly provoked acute attacks Callahan and Ingham (1939) used this vitamin in the treatment of acute attacks its prophylactic or curative value remains uncertain Of more certain value is the constant avoidance of the provocatives of gout not only the gastronomic but also the traumatic medicinal psychic and surgical provocatives The following regimen generally prevents postoperative gouty attacks use of high carbohydrate purine-free diet and cinchophen or a substitute for five days before and *also* for five days after operation (Hench) Postoperative attacks can also generally be prevented according to Talbott by prescribing daily 2 or 3 tablets of colchicine each grain $\frac{1}{120}$ two or three days before *and* after operation

Treatment of Chronic Gouty Arthritis—This may be prevented by the regimen outlined if not various types of physical therapy are required especially heat to foster resorption of urates Fever therapy or typhoid vaccine has been used occasionally Massage exercise and spa therapy must be used cautiously lest a cure crisis be evoked

Treatment of Tophaceous Ulcers—Large tophi on hands and feet may ulcerate and partially heal only to break down intermittently sometimes discharging urates for months occasionally they become infected Hence tophi in which ulceration is present or impending should be excised When debridement is done thoroughly prompt healing usually occurs Unless the tophus be small it is best before removal to institute the regimen for the prevention of postoperative gouty arthritis

Treatment of Renal and Other Complications—Gouty nephritis has certain distinctive clinical features Its treatment involves a generous intake of fluids (2 to 3 liters daily) restrictions of protein as necessary and continued efforts to combat the underlying gout Prevention of gouty calculi by urinary alkalinization was mentioned Non opaque to roentgen rays such calculi are usually small and pass without surgical intervention There is no specific treatment for the cardiovascular complications of gout

Prognosis, Results of Treatment.—Prognosis is best for those who develop gout late in life poorest for those with symptoms early in life Some patients have mild gout for years only symptomatic on rare occasions after special stress Patients after instruction may *fail* to *control their* gout because of half hearted application of the regimen (the most common reason) because their gout is uncontrollable by diet alone because of occupational or other trauma the unwitting use of medicinal provocatives or because of the presence of some chronic aggravating infection blood dyscrasia or metabolic fault (unsuspected diabetes or thyroid dysfunction) The correction of these factors usually results in improved control of the disease Cases of truly irreversible gout are not as common as supposed

Hench P S Chronic Arthritis (Chapter on Gout) In Barr David System of Applied Therapy Modern

Coffee and tea are permissible Veterans of gout insist that they can consistently tolerate certain alcoholic drinks but not others, since they cannot agree on which are harmless, the gouty novice should avoid all alcohol unless prepared to pay the price of personal experimentation

Physicians who espouse the allergic hypothesis consider the avoidance of purines less important than the avoidance of foods to which (regardless of their purine content) patients may be individually allergic as suggested by skin tests or by their apparent provocative effect The rationale of such restrictions is not yet clear but physicians should cater to established idiosyncrasies

Urate Eliminants —For the many patients who cannot control symptoms or hyperuricemia by diet alone the additional use of some urate eliminant is required Cinchophen seems to me to be the most effective and there is no exact substitute for it but because of its occasional toxicity it seems desirable first to try a substitute Salicylates augment urate excretion but generally have been considered inferior to cinchophen and ineffective except as mild analgesics unless large irritating doses are used But Jennings recently has concluded that salicylates are as effective as cinchophen in controlling pain and hyperuricemia He prescribed sodium salicylate 80 grains (5.3 Gm) daily, and sodium bicarbonate 120 to 150 grains (8 to 10 Gm) daily, three or four days a week to be continued indefinitely as interval therapy I have found this regimen very useful and generally but not always effective Others prescribe aspirin 60 to 80 grains (4 to 5.3 Gm) daily four days a week Another scheme based on Quick s report (1933) that glycine (amino acetic acid) augments the uricosuric' action of salicylates is this sodium salicylate 60 grains (4 Gm) and amino acetic acid 150 grains (10 Gm) daily three consecutive days a week

If the disease is not satisfactorily controlled by diets and these drugs I believe the intermittent use of cinchophen is justified except for those patients who are unwilling to accept the slight risk or have an idiosyncrasy to it The plan of Graham is generally used cinchophen 7½ grains (0 48 Gm) three times daily for three consecutive days each week The drug is used indefinitely but the dose is reduced or the drug withheld temporarily as control of gouty symptoms and of hyperuricemia permits If the blood uric acid becomes normal or nearly so the drug may be given for awhile only one or two days weekly in the usual dose or in smaller doses three days a week

Whenever cinchophen is given certain precautions such as ingestion of about 2 liters of fluid daily and of liberal amounts of carbohydrates must be taken Cinchophen carries a definite risk which some physicians never condone but which most students of gout consider justifiable if gout is uncontrolled otherwise Serious toxemia from cinchophen is after all rather rare especially in gouty patients The chances of serious or fatal intoxication from cinchophen in gouty patients are believed to be only a fraction of 1 per cent This risk must be contrasted with that of the disease itself in 10 to 15 per cent of cases gouty nephritis develops which is sometimes fatal and the incidence of renal colic from urate gravel and of cardiovascular lesions is notable Since the disease thus carries a much greater risk than its treatment by cinchophen it seems justifiable to assume the small risk of the latter *when necessary* to try if possible to prevent the articular renal and vascular consequences of gout Patients should be told of the risk of cinchophen toxemia and instructed to report such unusual symptoms as anorexia dyspepsia nausea loss of weight pruritus and jaundice to stop taking the drug at once and to report for special therapy consisting of administration of carbohydrates intravenously a high carbohydrate diet vitamin supplements and so forth

Alkalies —When urate eliminants are prescribed patients should take enough alkali to insure constant urinary alkalinity and thus prevent renal colic from the precipitation of urate gravel or stones in acid urine Patients can be taught to test the urine with litmus paper to determine the amount of alkali required this varies somewhat but potassium citrate 15 to 30 grains (1 to 2 Gm) three times daily or sodium bicarbonate 30 to 60 grains (2 to 4 Gm) three times daily generally suffices Occasionally gastro intestinal symptoms erro-

disposed subjects the disease may develop without the occurrence of any unusual provocation as in the case of an apparently normal child In subjects less strongly pre disposed contributing or provocative factors may play a role of greater or less importance according to the degree of the inherited weakness or predisposition

Heredity—Multiple incidence of diabetes in families has attracted attention for cen turies The percentage of families of diab etics in which it is possible to find other affected members varies with the material and method of study With the ordinary run of hospital cases it may range from 7 to 16 per cent In conditions more favorable for the procurement of data over longer periods of time higher figures are obtained e g Jos lin (2669 cases 1925–1928) 25 6 Barach (1030 cases), 44 5 John (630 cases 1939) 35 7 Lawrence (5 462 cases) 32 3 per cent (cited from Joslin) In families of 151 diab etic children who had survived the disease for fifteen years Joslin found an incidence of 52 per cent in 1940 (later 60 per cent) Studying the ratio of affected to nonaffected members in families of juvenile diabetics Priscilla White found 6 7 per cent as against 1 2 per cent in families of nondiabetic con trols In general harmony with the statistics of Umber Cammidge and Kern Berg and White have also observed that when the dis ease has appeared in one member of a pair of similar twins it has appeared in the mate in 65 and 63 per cent of cases as against 22 and 7 per cent in comparable pairs of dis similar twins When it is recalled that po tential diabetics may die before the disease appears or be yet unborn or may be living with an undiscovered diabetes when the his tory is taken such data lend color to the proposition that the disease is inherited or susceptible of transmission in every case

ANTICIPATION—It has long been known that when diabetes occurs in two or more members of the same generation of a given family it may develop in all in the same period of life There are striking exceptions in a minority group but in the majority of my cases the ages of onset have fallen within a span of fifteen years It was also observed by Bence Jones Gruber and Niessen (1865–1897) and later by Naunyn (1906) that when diabetes occurs in father and son it may appear at an earlier age in the son than in the father The same phenomenon may occur in uncle or aunt and nephew or niece and repeat in the following generation Thus the disease may appear in a first generation in the forties fifties or later in a second gen eration in the forties, thirties or twenties, in a third in the first or second decade The phenomenon is known as *anticipation* In 100 families that exhibited the disease in two or more generations Woodyatt and Spetz found evidence of the trend definite in 79 probable in 85 possible in 90 absent or reversed in 10 per cent The difference be- tween the ages of onset in two succeeding generations varied from less than five to fifty years but the average (in 90 cases) was twenty years When the trend occurs it leads in the course of two to four genera- tions to the appearance of the disease in childhood or youth and in such cases the juvenile diabetics are fruits of a *family* diab etes that has already existed in one or more *preceding* generations As a continuation of the trend to progeny of such juvenile diab etics would bring the age of onset into pre- natal time (diabetes *in utero* or nonconcep tion) the question arises as to whether diabetes is not a self limited disease which runs its course in a given family and tends to extinction in a limited number of generations

MENDELIAN RATIOS—Hereditary phe nomena are too numerous and complex to be fully explained by any known laws Whether diabetes is transmitted on men delian lines and if so as a recessive or domi nant trait is a much discussed theme On the basis of data on 851 families of diabetic children Pincus and White support the con ception of simple recessiveness in the men delian sense The theory implies that if two parents are diabetic or potentially so 100 per cent of their children will develop the disease if they live long enough if one parent is diabetic and the other a carrier 50 per cent if both are carriers 25 per cent if one is normal and the other a carrier 0 per cent (but then all would be carriers) The incidence found in children of crosses of the three types were less than the expec tancy in every case but with corrections for five possible sources of error on the basis of probabilities derived from statistics and on the assumption that both parents of any

DIABETES MELLITUS

Definition—Diabetes mellitus is an inheritable constitutional disease of unknown cause characterized by continuing hyperglycemia and glycosuria and in the more advanced stages by acidosis (*ketosis*) These signs are expressions of disturbed relations between chemical changes of carbohydrate protein and fat in the body and especially those that produce or consume sugar and the acetone bodies Of the many factors involved in the equilibrium of these reactions in normal conditions the particular ones of the greatest interest in this disease are the hormones of the islets of Langerhans the anterior pituitary and adrenal cortex the two latter increased and the former diminished in the relative sense It appears however that a deficiency of insulin (relative or absolute) is to be considered as the basic determining factor The disease is further distinguished especially in the middle and later decades of life by arterial changes (*arteriosclerosis*) and a variety of other manifestations not directly relatable to the hyperglycemia, glycosuria etc

History—Allusion to polyuria occurs in records of great antiquity The name diabetes—from the Greek (διαβαίνειν to run through διαβήτης siphon)—appears in a work of Aretaeus (first century A. D) The polyuria according to Galen was due to a state of the kidneys like that of the bowel in diarrhea, which permitted drink to pass through the body without alteration In the Occident this doctrine still survived at the end of the fifteenth century The sweet taste of the urine was known in India as early as the fifth or sixth century A thousand years later it enlisted the interest of Thomas Willis in England (d 1675) and in 1775 Dobson evaporated diabetic urine and recovered a sugar This was identified with the sugar of grapes (glucose) by the chemist Chevreul in 1815 After Dobson s discovery Cullen distinguished the two conditions known thereafter as diabetes mellitus and diabetes insipidus respectively and Rollo treated a famous case by "a diet of animal food as rancid as possible with the view of preventing fermentation of sugar in the stomach" Between 1849 and 1877 Claude Bernard developed his original concept of the liver as the site of sugar production and of diabetes as due to an overproduction of sugar in the liver (*glycogenic theory*) In 1889 to 1892 von Mering and Minkowski proved that extirpation of the pancreas invariably results in diabetes and that the pancreas produces an internal secretion necessary for the *normal metabolism* of glucose It was not until 1921 that Banting and Best in the laboratory of McLeod prepared extracts of the pancreas that could be proved to contain the active principle known thereafter as *insulin* A new chapter in the history began in 1930 with the observation of Houssay that hypophysectomy markedly alters the manifestations that ordinarily follow pancreatectomy Whereas the latter alone leads to hyperglycemia glycosuria, acidosis and death in dyspneic coma—animals from which both glands have been removed show less hyperglycemia and glycosuria and also little or no acidosis In fasting the glycosuria disappears and the animals die in hypoglycemia Long and Lukens observed similar pictures in pancreatectomized adrenalectomized animals It was then demonstrated by Young in 1937 that it was possible to produce permanent diabetes in dogs by the administration of extracts of the anterior lobe

Etiology—Injuries and diseases of known etiology effecting the destruction of a sufficient portion of the pancreas account for a small proportion of clinical cases of diabetes When recognized these are classified under the heading of *pancreatic diabetes* as in contradistinction to *pure (or spontaneous) diabetes* The cause of the latter is not known It is clear however that etiologic factors of decisive importance are susceptible of hereditary transmission Naunyn favored the conception of diabetes as the expression of an *individual inherited disposition* having its seat in the nervous system (*neuropathic disposition*) According to this view in sufficiently strongly pre

diabetes in a not inconsiderable fraction of cases The same is true of psychic shocks and severe emotional disturbances Depressive emotions anxieties fears unhappiness arising from various causes—such as domestic infelicities financial losses etc are notoriously capable of provoking the onset Various injuries and diseases of the central nervous system such as concussions skull fractures apoplexies brain tumors etc may produce a glycosuria which proves to be transient and not diabetic or may serve to provoke the onset of true diabetes

Infections.—The onset of diabetes often occurs during or after an acute infection In 1918 and 1919 many of the new cases of diabetes appeared during or after influenza But in proportion to the incidence of influenza diabetes was rarely a complication Certain types of acute upper respiratory tract infections that prevail at some seasons are more potent than others to aggravate an existing diabetes or provoke its onset Generally speaking any infection may aggravate a diabetes Very mild forms of diabetes may be brought to light during an attack of tonsillitis sinusitis cystitis cholecystitis etc and disappear with the cure of the infectious process Chronic infections may contribute to the maintenance of glycosuria Infections that lead to pancreatitis may produce pancreatic diabetes But there is no substantial support for an infectious theory of true diabetes The observation that the tolerance of a diabetic may improve in the course of tuberculosis recurs in the literature

Syphilis—Syphilis plays no important role

Morbid Anatomy—As early as 1788 Cawley reported stone and atrophy of the pancreas in a case of diabetes and the repeated findings of morphologic changes was one of the clues that led to Opie s establishment of the relation of the islets of Langerhans to diabetes

The following tabulation condensed by Lukens from a table of Warren s with added data on fibrosis shows the lesions of the pancreas that may be found

From these figures it is seen that 80 per cent of diabetics have some island lesions while 20 per cent have been classified as normal and 61 per cent have had some degree of generalized pancreatic fibrosis usually interacinar In nondiabetics of corresponding ages only 16 per cent had any island lesions and only 29 per cent had pancreatic fibrosis (Lukens)

AUTHOR	TOTAL CASES	NORMAL	HYALINE	FIBROSIS	HYDROPIC DEGENERATION	OTHER LESIONS	GENERAL PANCREATIC FIBROSIS
Cecil	90	11	27	49	0	3	67
Waller	29	8	4	12	0	5	
Gill and Logan	142	11	30	79	0	22	
Herxheimer	97	22	38	13	0	0	
Warren	484	127	200	1 9	22	133	269
Total	842	179	299	232	22	163	

Since the discovery of experimental pituitary diabetes Lukens and Dohan and others have studied the evolution of islet lesions in this condition from primary swelling and hydropic change to ultimate fibrosis or disappearance and a reversal of the process under appropriate measures (discontinuance of pituitary administration of insulin) before the fibrotic stage is reached

Changes in other endocrine glands besides the pancreas are often found in autopsy material but none are established as constant or distinctive at the present time Eosinophile or basophile pituitary adenomas in acromegaly or Cushing s syndrome are often associated with diabetes but are absent in most cases Diabetes may be associated with adrenal tumors but changes in the adrenals have been missed in most cases

Atherosclerosis or *atheroma* are constant after the third decade of life Warren Root, *et al* found evidence of it in earlier life At any particular period of life the aging of the arteries of a diabetic may be 10 per cent greater than in the average normal person (H E Eisele)

Physiology—Glucose is continually entering the body from the food and tissues continually undergoing chemical change and elimination If S is the rate of glucose *supply* from all sources C the rate of *chemical change* E the rate of *excretion* and B the *body content* then in normal conditions E

diabetic child are carriers (if not actually or potentially diabetic) the figures agree

Overindulgence and Obesity—In India in the fifth or sixth century Suzruta described diabetes as a disease suffered principally by the rich, because of their overindulgence in carbohydrates (rice flour and sugar), and since the end of the seventeenth century this view has recurred repeatedly The association of obesity and diabetes has long been known Of 1000 cases observed by Joslin 77 per cent were overweight as judged by a standard height weight scale It is a well known fact that reducing the weight of an obese diabetic may increase the tolerance for carbohydrate and that tolerance may be lowered by overfeeding In a statistical study of subjects who exhibited glycosuria during tolerance tests, Newburgh observed that about a half were obese and over thirty years of age After the weights of such subjects had been reduced to normal by under nutrition more than 90 per cent were aglycosuric on diets containing 300 Gm carbohydrate and then exhibited normal tolerance curves Abnormalities recurred with recurring obesity and disappeared again with reductions of weight In such cases we are dealing Newburgh suggests with a clinical entity in which the obesity is the principal abnormality and hyperglycemia is a secondary phenomenon According to Long analogous phenomena are observed in experimental obesity in rats The conversion of sugar into fatty acids which is possibly a process that occurs mainly or entirely in the liver (see Utilization) is one of the main means that the body possesses for the disposition of sugar and a large factor in tolerance It would seem possible that as accumulations of fat (especially in the liver) approach a limit the process is retarded It is apparent therefore that obesity may hasten the onset of diabetes in a predisposed subject, aggravate an existing diabetes or lower the tolerance of a nondiabetic These and the high incidence of obesity in diabetics past a certain age are the main supports for the conception that obesity *causes* diabetes However obesity is not common in young diabetics many obese subjects never develop true diabetes and it would seem probable that obesity in diabetic stock is in the nature of associated endocrinopathy

Other Endocrinopathies—Glycosuria associated with hyperglycemia is a common accompaniment of various endocrinopathies and may be produced experimentally with various gland extracts (pituitary adrenal, thyroid etc) *Vice versa*, many patients with true diabetes exhibit evidence of disorders of other endocrine glands besides the islets Some types of obesity may be so considered, also arterial hypertension, impotence in males sterility in females hyperthyroidism hypercalcemia etc In both connections the pituitary is important as well as the adrenals gonads and thyroid The diminution or abolition of the glycosuria and ketosis of pancreatic diabetes that follows hypophysectomy, the diabetogenic and ketogenic activity of certain fractions derivable from the hypophysis, the evidence of pituitary dysfunction among diabetics, and the work of Young showing that a permanent diabetes can be produced by the administration of large quantities of anterior lobe extracts all indicate that in diabetes the pituitary gland is always involved

Arteriosclerosis—After the third decade of life arteriosclerosis is increasingly frequent in diabetics and is found with great uniformity in middle aged and elderly subjects It has been regarded as causative through the production of organic lesions (atrophy of the pancreas central nervous system lesions etc) But the arterial disease of diabetics is often most marked in the mildest cases and absent or insignificant in the most severe forms seen in younger subjects, and can scarcely be viewed as a causative factor

Gout—The association of gout and diabetes has been remarked on in the literature Charcot and his pupils held that the inheritance of a common underlying character could lead to the development of both conditions The writer concurs with the view of Pratt that in this country at least the two are not often associated

Race—Statistical studies generally confirm the view that the incidence of diabetes in Jewish families exceeds that of any others Variations of the incidence in Chinese Japanese Negroes Indians and others are less definitely established

Nervous and Emotional Factors—Severe nervous shocks such as may result from injuries exposures etc precede the onset of

undergoes chemical change parts are disposed of by (1) *direct oxidation* to CO_2 and water (2) *polymerization* to glycogen and (3) *reduction* to fatty acid (and fat)

DIRECT OXIDATION occurs continuously in all the tissues but as the muscles represent the great bulk of actively oxidizing tissue it occurs in muscles on the largest scale With the low rates of supply that prevail in fasting it may account for the disappearance of nearly all the sugar that enters the blood With the higher rates of supply that prevail after meals the rate of direct oxidation rises but it cannot be driven above a normal limit As this limit can be exceeded (2 or 3 1) by the rates of absorption that prevail after meals some fraction of a post prandial sugar supply is necessarily disposed of by other means

POLYMERIZATION to glycogen occurs on the largest scale in the liver It serves especially for the quick disposition of excesses of sugar but has definite limits The glycogen content of an adult liver is rarely as high as 15 per cent Even 7 per cent (*i e* 210 Gm per 3000 Gm liver) is a high normal figure This may approximate half of the total body content When saturation is reached the process stops and glycogen once formed can only be disposed of by reconversion into sugar So glycogen formation while important in the regulation of the blood sugar level can only account for the temporary disposal of a small quantity of sugar that might be stated roughly as about a pound

REDUCTION to fatty acid is also a process that occurs largely in the liver* but unlike glycogen fatty acid can be further metabolized without reconversion into sugar It is susceptible of direct oxidation as such or of storage as fat in enormous amounts with no more than an approach to saturation and such fat can burn like fat derived from any other source So reduction to fatty acid is really a step in a process of INDIRECT OXIDATION and a major means for disposing of continuing high supplies In this connection it should be noted that whether glucose burns directly to CO_2 and water or is first reduced to fatty acid (and/or fat) and then burns as such the R Q for the whole process is exactly the same in either case Studies of muscles of depancreatized animals by tissue slice and similar methods show that they retain the ability to oxidize glucose and suggest that this ability may approach the norm If this is true it would seem clear that the direct oxidation of glucose in the muscles of the diabetic may not be impaired to a sufficient extent to account for the diabetic state Still such observations would not warrant the conclusion that the oxidation of glucose by any or all methods is not impaired and that we must, therefore fall back on the old conception of an overproduction of sugar from fat As stated a large fraction of all the sugar that enters the body may be changed to fat and burned as such by the process of indirect oxidation Even if the capacity for direct oxidation were intact a limitation of the ability to convert sugar to fat could still account for the diabetic state

* Writer s interpretation not beyond debate

Glucose Excretion —The normal urine is never strictly sugar free The percentage of sugar in normal urine is of the same order of magnitude as that in the blood When a physician tells a patient there is no sugar in the urine but too much in the blood he simply means that the urine when tested with a qualitative reagent such as Benedict s or Haines gives a negative test while the blood when examined by a more refined method such as the Folin Wu blood sugar procedure shows more than the normal percentage of sugar But both normal blood and normal urine yield negative tests with the ordinary qualitative test solutions and both show sugar when examined by similar colorimetric methods To clear up a common misconception Benedict proposed the term *glycuresis* to denote the normal and the use of glycosuria to denote an abnormal excretion of sugar

GLYCURESIS —In over 200 000 examinations of twenty four hour urines carried out in the writer s laboratory by the Folin Berglund method for the quantitative estimation of the sugar of normal urine those that have given negative qualitative tests have shown reducing substances equivalent to 0 1 to 1 0 Gm glucose in the vast majority of all cases Negative qualitative sugar tests are at times compatible with excretions as high as 1.5 to 2 0 Gm per day The average normal urine shows 0 2 to 0 9 Gm per day An excretion of 0 9 Gm is

is minimal, C approaches S, and B approaches constancy at a normal level But if S is greater than C, there is an increase of B and (barring simple retentions) an increase of E Abnormal increases of B and E are characteristic of the diabetic state Clinical diabetes could be due theoretically either to an abnormal increase of S from endogenous sources while C remained normal (*'over production'*), or to a depression of C below the normal, while S remained normal (*under consumption'*) The former would necessarily imply a massive production of sugar from fat But any production of sugar from fat in any condition remains hypothetical at the present time and the great weight of evidence favors the view that we are dealing with a depression of some phase or phases of the utilization of sugar

Glucose Supply—The glucose supply is derived from carbohydrate protein and fat either of the tissues or of the food or both depending upon the state of nutrition Thus on maintenance diets it comes from the food on submaintenance diets partly from the food and partly from the tissues and in fasting entirely from the tissues Any carbohydrate that is utilized on the larger scale in the body may be made to appear in the urine as glucose if it is administered to a diabetic and under favorable experimental conditions may be recovered almost quantitatively as glucose Thus any utilizable carbohydrate is either glucose to begin with or capable of conversion into glucose either in the processes of digestion (as in the case of starches dextrins etc) or of the intermediate metabolism (galactose levulose etc) or of both (cane sugar, lactose, etc) It would appear that glucose (or a closely related unstable substance in chemical equilibrium with it) may be the only form of carbohydrate that can be directly utilized on the larger scale in the animal body Thus 100 Gm of utilizable carbohydrate may introduce into the body roughly 100 Gm of glucose *Protein* yields by digestion or in the course of catabolism a medley of amino acids of which some are convertible into glucose Lusk's completely phlorhizinized meat fed dogs excreted glucose and nitrogen in the ratio of 3 65 1 If there were no oxidation of sugar in the body and if all of the sugar that appeared in the urine were derived from the protein contained in the meat and none from fat, this would imply that 100 Gm of muscle protein introduced into the body 58 Gm glucose In totally phlorizinized *fasting* dogs the D N ratio may linger in the neighborhood of 3 1 and then gradually fall to around 2 4 as exitus approaches and similar ratios around 2 8 (the Minkowski ratio) may occur in the fasting depancreatized dog With the same provisos these ratios would imply that 100 Gm of body protein may yield between 40 and 50 Gm sugar It is now known however that the oxidation of sugar is not abolished in these conditions Removal of the hypophysis or the adrenals of depancreatized animals (Houssay, Long Lukens) and studies of isolated tissue slices and so on show that sugar still burns especially in the muscles in so called 'total diabetes And as glycerol is convertible into glucose it is probable that some sugar is derived from the glycerol of neutral fats (which represents about 10 per cent of their weight) So we cannot state the exact quantity of sugar that protein may yield However as the oxidation of sugar in the tissues can only be driven to a normal limit all sugar supplied in excess of a limit may be recovered quantitatively in the urine and it is probable that the Lusk figure (58 per cent) observed in meat fed dogs is more nearly correct than figures obtained in the fasting state For clinical purposes some formula is needed for rough estimations of the available glucose in different mixtures of C P and F In the older equation $G = C + 0\ 58\ P + 0\ 1\ F$ in which G is the quantity of available glucose the protein figure is probably low and the figure for fat is open to some question Empirically however it works out as well as any other that we can state at the present writing

Glucose Utilization—In normal conditions whatever the glucose supply may be it all disappears within the body except for a trace that escapes in the urine A small fraction may be *retained* temporarily as glucose The remainder undergoes *chemical change* If S is the rate of supply R the rate of retention E the rate of excretion and C the rate of chemical change then $S = C + E \pm R$ and when R and E are minimal C approaches S Of the sugar that

phenomena encountered in the study of diabetes

In the blood sugar regulatory activity of the liver alternate storage and hydrolysis of glycogen are the chief factors involved in short periods of time However as stated (see Utilization), conversion of sugar into fatty acids may also be involved although probably not as a reversible process

Body Content of Glucose.—The sugar of the body is almost wholly in a state of simple aqueous solution in the lymph and blood Even the sugar of the cells is mainly in the cell lymph Being freely diffusible it tends to maintain the same concentration in the blood and lymph The concentration in the blood is the measure of that in the plasma lymph The blood sugar percentage × the total volume of the blood and lymph gives a fair approximation of the body content In an average normal subject it may amount to a matter of some 7 to 10 Gm The total quantity is divided between the blood and lymph in proportion to the relative volumes of the two As in clinical circles it is rather customary to consider the blood sugar percentage as a direct indication of the total quantity of sugar in the body it is well to recall that while the total blood volume varies within relatively narrow limits in health and disease the volume of the lymph is subject to much wider variation Even in normal condition the lymph volume is as variable as that of the urine and variations may be enormous in pathologic states Compare for example the total volume of lymph in a dehydrated subject with that of another in general anasarca with perhaps gallons of fluid in the abdomen alone Observed variations of the blood sugar level can only be regarded as in simple direct proportion to the body content when the ratio of the volumes of the blood and lymph remains the same

Ketosis—The three substances β hydroxy butyric acid CH_3 CHOH CH COOH aceto acetic acid CH_3 CO CH_2 COOH and acetone CH_3 CO CH_3 are known collectively as the acetone bodies In normal subjects on diets containing enough carbohydrate only traces appear in the blood and urine but in fasting (usually after the second day) during subsistence on diets sufficiently low in carbohydrate and high in fat and in a number of pathologic states gross quantities appear in the blood and urine As the two acids of the group are capable of causing the same chain of events that follow administrations of mineral acids the condition was first described and was the first to be described as acidosis But to distinguish the anomaly of the fat metabolism from other forms and phases of acidosis the term ketosis is in current use Pollack has suggested ketotic acidosis as a better term as the acetone bodies consist in the main of the hydroxy acid and as their effects are due to the acid groups These substances spring from fats and proteins The immediate precursor is butyric acid CH_3 CH_2 CH_2 COOH (or a closely related 4-carbon group) derived from the higher fatty acids and also from certain amino acids in the course of their oxidative catabolism

It has long been known from Embden s perfusions of surviving organs that ketogenesis occurs mainly or wholly in the liver and from intravenous injections that material quantities of aceto acetic and β hydroxy butyric acids introduced into the blood stream disappear and are doubtless burned As shown by Wilder (1914) it is only when the rate of intravenous injection exceeds a limit that appreciable quantities appear in the urine Stadie s studies of tissue slices by the Warburg method have shown that the muscles are the principal site of the oxidation and that the rate of oxidation in the muscles cannot be driven above a normal limit So the acetone bodies are produced in the liver destroyed in the muscles and when the rate of production exceeds a limit they appear in excess in the blood and urine

As stated above ketosis occurs in various pathologic states *e g* cyclic vomiting or migraine in children milk sickness or eupatorium poisoning in cattle and man in other intoxications and some forms of infection affecting the liver and in diabetes The calorimetric studies of F G Benedict in inanition and fasting show that ketosis first appears in the normal fasting subject when the rate of carbohydrate oxidation and the quantity of glycogen remaining in the body have both fallen to low levels Studies of dietary acidosis by Zeller and others have shown that on isocaloric isoprotein maintenance diets containing different propor

at the upper limit of the norm, of 1 0 Gm or over above the norm These quantities include a fermentable and a nonfermentable fraction The latter seldom exceeds 0 1 to 0 15 Gm The fermentable fraction falls in fasting It may approach 0 in the fasting state but it rises with starch or glucose feedings and (except in cases of alimentary levulosuria) doubtless consists mainly or wholly of glucose After doses of 50 to 100 Gm glucose the excretion curve shows a rise and fall that normally follow the rise and fall of the blood sugar curve (occasionally after a one to three hour lag) The total output for three hours multiplied by 8 *(or for six hours by 4) is usually less than* 1 0 to 2 0 Gm in normal conditions In the carrying out of tolerance tests the excretion should be plotted by a sensitive method as well as the usual blood sugar curve It not infrequently happens that a subject will show an abnormally high and protracted excretion with a normal or doubtful blood sugar curve

GLYCOSURIA —An excretion of 1 Gm sugar in twenty four hours is usually abnormal and if the sugar is glucose we speak of glycosuria In diabetes the excretion may rise from 1 to 200 Gm or more depending on the severity of the case the diet and so on In the most severe cases and especially in the presence of acidosis the glycosuria *may persist in fasting and the* D N ratios may then approximate those of totally depancreatized or phlorizinized dogs In a great majority of cases of human diabetes the glycosuria can be stopped by partial or total diet restriction If when this has been done the glucose supply is progressively raised by successive additions of a fixed increment to the diet the excretion of sugar may at first remain constant or rise very slightly within normal limits But sooner or later one increment causes an abnormal excretion and we speak of having reached a *tolerance limit* Further additions to the diet thereafter cause progressive increases of the glycosuria until a point is reached at which all of the last increment appears in the urine (*utilization limit*) Thus with a glucose supply rising as a straight line the excretion curve may remain nearly level or rise very little to a certain point and then show a progressive upward trend This type of curve is characteristic of true diabetes In *renal glycosuria* and *glycosuria of pregnancy* there is no definite break in the excretion curve—the output of sugar representing very nearly the same percentage of any supply that may be given There are cases of diabetes in which the critical point in the excretion curve is ill defined and also the acceleration of the sugar excretion after the tolerance has been overstepped These have been referred to as cases with flexible tolerance limits' or 'renal factors etc As the glycosuria shows less than the usual variation with high and low diets and insulin doses they are sometimes attributed to *insulin resistance But all phenomena en*countered in diabetes are not explainable on the basis of ups and downs of the insulin secretion We must also consider other factors and especially disorders of the *regulation* of blood sugar levels (See Blood Sugar Concentration)

Blood Sugar Concentration —In normal subjects the concentration of sugar in whole blood varies in fasting from 0 06 to 0 12, average 0 1 per cent (100 mg per 100 cc) After a dose of 50 to 100 Gm glucose it rises and commonly reaches a peak at 0 12 to 0 17 per cent within the first *hour and* falls to or *below* the original level within two hours The fall of the blood sugar may occur in the course of continuing absorption *and is evidence of the operation of a blood sugar regulating mechanism* The work of Mann Soskin and associates with hepatectomized animals and isolated livers shows that this mechanism resides in the liver and that the liver is set to store or secrete sugar as the blood sugar level rises above or falls below a definite norm In accordance with this view an elevation of the blood sugar to a certain level above the norm *stops* secretion and starts storage of sugar by the liver while a fall of the blood sugar to a certain level below the norm reverses the process In health the mechanism is set to maintain the concentration of sugar in the blood at levels within the normal limits But in abnormal conditions it may be set to maintain a hyper or a hypoglycemic state or become so deranged that it fails to regulate the blood sugar level *This conception is important for the interpretation of blood sugar curves variations in tolerance and other*

to precede it and perhaps contribute to its development As shown by Priscilla White 90 out of 100 diabetic children were above the average in height before the onset of diabetes A certain number of patients give histories of having gained weight rapidly in the period preceding the onset of glycosuria Thus a woman who had never weighed more than 115 pounds up to the age of thirty eight gained 18 pounds in her thirty ninth year for no apparent reason as she was a housewife who lived at home and had not changed her habits or daily routine She then suddenly developed a severe diabetes Males may show the same phenomenon Some patients show evidences of the neuro pathic disposition before the onset of glycosuria A certain physician who was tall and rugged and had weighed 180 pounds became diabetic at twenty six This patient insisted that he was aware of a constitutional change two years before the appearance of glycosuria At twenty four he had become unaccountably nervous irritable depressed fatigable and unlike himself This had led to repeated physical examinations in which nothing abnormal was found in the urine In some cases symptoms of hypoglycemia antedate glycosuria or alternate with it However all such symptoms are indeter minate and it is not possible at present to diagnose diabetes before the occurrence of glycosuria

Diabetes Decipiens —This name is applied to diabetes without any of the cardinal symptoms other than glycosuria It may exist for indefinite periods However even a slight glycosuria with the attendant hyper glycemia may cause subjective sensations Diabetic patients who are accustomed to keeping the urine sugar free by diet and insulin not infrequently know when they are passing sugar by various sensations—such as feelings of pressure over the eyes head aches neuralgias tiredness etc

Commoner Symptoms —The classic symp toms of diabetes are excessive thirst and water drinking (*polydipsia*) the voiding of excessive volumes of urine (*polyuria*) which ordinarily implies increased frequency of urination as well excessive appetite and eating (*polyphagia*) *loss of weight* and general *weakness* Other very common symp toms are *itching of the skin balanitis* or *vulvovaginitis constipation, somnolence dimness of vision* and *muscular pains* Acid osis with acid intoxication leads to the appearance of additional symptoms forming a definite group by themselves A great variety of other symptoms or complications associated with changes in the arterial and nervous systems occur with increasing fre quency after the age of thirty years Some of the commoner of these are *impotence loss of the tendon reflexes neuralgias neuritis perforating ulcer* (*mal perforant*) *cataract diabetic retinitis obliterating angiitis gan grene of the extremities*

Polydipsia —Glucose like salt and other freely diffusible water soluble substances has an affinity for water An excess of glu cose in the body creates a demand for extra water which may be felt as thirst and met by an increased water intake The introduc tion into the body of an excess of sugar results in a shifting of water from the cells to the lymph and blood causing relative tissue dehydration and the symptom thirst

Polyuria —The movement of sugar through the body and into the urine in the form of aqueous glucose solution involves the movement of more or less water In ex periments with continued intravenous injec tions of glucose into dogs the highest urinary sugar concentrations observed by the writer and Hannah Felsher have been between 12 and 13 per cent These concentrations were only observed with marked dehydration of the body The literature contains reports of the same (and even higher) concentrations in diabetes With concentrations of 12 to 13 per cent the elimination of 1 Gm of sugar entails the excretion of not over 6 25 to 8.5 cc of water During intravenous glucose injections the urinary sugar concen tration frequently rises to 8.5 to 9 per cent and may remain persistently at this level only exceeding it when the body has lost sufficient water These latter concentrations are not rarely observed in diabetes and imply the excretion of not over 11 to 12 cc of water per gram of glucose Thus even the excretion of 20 to 30 Gm of glucose does not necessarily increase the urine volume output by more than 240 to 360 cc In cases of relatively mild diabetes in which the power is retained to utilize considerable quantities of glucose and in cases of severe

tions of carbohydrate and fat, ketosis first appears when the ratio of fat to carbohydrate calories approaches the neighborhood of 0 1 or when the Gm of fat, carbohydrate and protein are in about the proportions $F = 2C + 0.5P$ as stated by the writer This is true of the average normal subject variations occurring in various physiologic and pathologic states (pregnancy child hood, some forms of obesity and so on) In fasting and dietary acidosis the administration of small quantities of carbohydrate (50 75 100 Gm) is often sufficient to stop the process and this raises the question as to how carbohydrate exerts its antiketogenic effect There are a number of views

1 The older view to the effect that fatty acids are susceptible of oxidation in more than one way that the oxidation of a given quantity of fatty acid may yield different quantities of acetone bodies in different conditions and that sugar in the course of its oxidation affects the character of the fatty acid oxidation While the oxidation of sugar may spare the oxidation of a calorically equivalent amount of fat and thus diminish ketosis by lowering the magnitude of the fat metabolism it has in addition a specific antiketogenic effect It has been believed for a long time that while alcohol may lower an existing ketosis in some conditions still calorie for calorie it is less effective than sugar The experimental basis for this belief has not been reviewed in recent times However alcohol was much used in the treatment of diabetic acidosis in the pre insulin era and with some success but less than would be expected if alcohol were as antiketogenic as sugar One hundred Gm alcohol a glass of whiskey a moderate high ball once in six hours are the caloric equivalent of 175 Gm sugar an amount which if burned is sufficient to bring most patients out of coma But alcohol never solved the coma problem

2 The view of Stadie that the oxidation of a given quantity of fatty acid produces the same quantity of acetone bodies in different conditions, that the oxidation of sugar spares the oxidation of its caloric equivalent in fatty acids and has no other antiketogenic effect In other words ketosis depends in the main on the absolute magnitude of the fat metabolism As some of Benedict's subjects in fasting acidosis burned in the neighborhood of 2.5 Gm. fat per Kg per day this figure may be taken as an indication of the absolute magnitude of the fat metabolism which is sufficient to determine acidosis in accordance with this view

3 The view represented by Mirsky and Soskin that the antiketogenic action of carbohydrate is not due at all to its oxidation but to its presence as glycogen in the liver It may be noted however that conditions existing in a glycogen filled liver are scarcely compatible with diminished oxidation In accordance with the old view it would be the oxidation of sugar that occurs in the liver (not in the muscles) that exerts the antiketogenic effect, as pointed out by the writer in 1915 but not emphasized in Shaffer's development of the theme

Acidosis.—In the course of a ketosis large quantities of acid enter the system from endogenous sources In the fasting ketosis some 10 to 15 or 20 Gm may appear in the urine in twenty four hours In diabetic ketosis the quantity may rise to 30 50 100 or in some cases 200 Gm or more A minor part of this acid is excreted in a free state A second fraction combines with ammonium and appears in the urine as ammonium salts increasing the ammonium content of the urine (normal 0.5 to 1.5 abnormal 2 0 to 4 0 or even 7 0 Gm in twenty four hours) The balance combines with bicarbonates contained in the plasma lymph and appears in the urine as salts of inorganic base For the disturbance of the acid base balance etc see the chapter on *Acidosis* We may simply repeat here that in normal conditions the total combined plasma CO_2 varies around 60 volumes per cent falling to as low as 8 to 10 in extreme acidosis

Clinical Symptoms and Signs—*Preglycosuric Manifestations*—Before the appearance of glycosuria *diabetes* can scarcely be proved to exist Still in a certain percentage of cases symptoms or signs of abnormality may precede the appearance of glycosuria and raise the question as to whether they should be regarded as preglycosuria manifestations of the underlying disease or merely as those of some other disorder not specifically related to diabetes but which happen

to precede it and perhaps contribute to its development As shown by Priscilla White 90 out of 100 diabetic children were above the average in height before the onset of diabetes A certain number of patients give histories of having gained weight rapidly in the period preceding the onset of glycosuria Thus a woman who had never weighed more than 115 pounds up to the age of thirty eight gained 18 pounds in her thirty ninth year for no apparent reason as she was a housewife who lived at home and had not changed her habits or daily routine She then suddenly developed a severe diabetes Males may show the same phenomenon Some patients show evidences of the neuro pathic disposition before the onset of glycosuria A certain physician who was tall and rugged and had weighed 180 pounds became diabetic at twenty-six This patient insisted that he was aware of a constitutional change two years before the appearance of glycosuria At twenty four he had become unaccountably nervous irritable depressed fatigable and unlike himself This had led to repeated physical examinations in which nothing abnormal was found in the urine In some cases symptoms of hypoglycemia antedate glycosuria or alternate with it However all such symptoms are indeter minate and it is not possible at present to diagnose diabetes before the occurrence of glycosuria

Diabetes Decipiens —This name is applied to diabetes without any of the cardinal symptoms other than glycosuria It may exist for indefinite periods However even a slight glycosuria with the attendant hyper glycemia may cause subjective sensations Diabetic patients who are accustomed to keeping the urine sugar free by diet and insulin not infrequently know when they are passing sugar by various sensations—such as feelings of pressure over the eyes head aches neuralgias tiredness etc

Commoner Symptoms —The classic symp toms of diabetes are excessive thirst and water drinking (*polydipsia*) the voiding of excessive volumes of urine (*polyuria*) which ordinarily implies increased frequency of urination as well excessive appetite and eating (*polyphagia*) *loss of weight* and general *weakness* Other very common symp toms are *itching of the skin balanitis* or *vulvovaginitis constipation somnolence dimness of vision* and *muscular pains* Acid osis with acid intoxication leads to the appearance of additional symptoms forming a definite group by themselves A great variety of other symptoms or complications associated with changes in the arterial and nervous systems occur with increasing fre- quency after the age of thirty years Some of the commoner of these are *impotence loss of the tendon reflexes neuralgias neuritis perforating ulcer* (*mal perforant*), *cataract diabetic retinitis obliterating angiitis gan grene of the extremities*

POLYDIPSIA —Glucose like salt and other freely diffusible water soluble substances has an affinity for water An excess of glu cose in the body creates a demand for extra water which may be felt as thirst and met by an increased water intake The introduc tion into the body of an excess of sugar results in a shifting of water from the cells to the lymph and blood causing relative tissue dehydration and the symptom thirst

POLYURIA —The movement of sugar through the body and into the urine in the form of aqueous glucose solution involves the movement of more or less water In ex periments with continued intravenous injec tions of glucose into dogs the highest urinary sugar concentrations observed by the writer and Hannah Felsher have been between 12 and 13 per cent These concentrations were only observed with marked dehydration of the body The literature contains reports of the same (and even higher) concentrations in diabetes With concentrations of 12 to 13 per cent the elimination of 1 Gm of sugar entails the excretion of not over 6 25 to 8.5 cc of water During intravenous glucose injections the urinary sugar concen tration frequently rises to 8 5 to 9 per cent and may remain persistently at this level only exceeding it when the body has lost sufficient water These latter concentrations are not rarely observed in diabetes and imply the excretion of not over 11 to 12 cc of water per gram of glucose Thus even the excretion of 20 to 30 Gm of glucose does not necessarily increase the urine volume output by more than 240 to 360 cc In cases of relatively mild diabetes in which the power is retained to utilize considerable quantities of glucose and in cases of severe

diabetes on insulin treatment *very considerable glycosuria may occur without abnormal diuresis* As pointed out by Lusk Fisher and Wishart, *sugar in the process of burning or storage tends to hold water in the body* as against the diuretic action of sugar that escapes oxidation and storage Very often however the output of water per gram of sugar rises much higher than 12 cc and with even moderate glycosuria the urine volume may be 3 or 4 liters in twenty four hours and with high sugar outputs 5 liters and upward Outputs of 10 to 12 liters occur but are exceptional Reports in the literature of excretions of 20 liters and over are not beyond bounds of possibility (Under intravenous injection of glucose dogs weighing 10 kilos may excrete 300 cc per hour *i e* at the rate of 50 liters per 70 kilos per twenty four hours)

POLYPHAGIA —When the fuel value of the diet minus that of the sugar lost in the urine is insufficient for maintenance this commonly leads to hunger and an increased consumption of food However various factors—psychic nervous toxic etc may reduce the appetite The onset of acid intoxication commonly leads to anorexia or nausea

LOSS OF WEIGHT —Losses of weight in diabetes are due in the main to undernutrition Such undernutrition may be due wholly to losses of energy corresponding to the sugar excreted in the urine Such losses of weight are to be differentiated from those that are caused by diet restrictions and those that are attributable to losses of water The discovery of a diabetes (or an innocent type of glycosuria) may lead the physician or the patient himself to limit the diet enough to determine a loss of weight when a lesser loss or none at all would have resulted from the disease Also in cases of suddenly developing severe diabetes with polyuria the output of water in the urine may for a time exceed the intake as water formerly held in the tissues is shifted into the blood and urine leaving the tissues in a state of relative dehydration And thereafter even with the reestablishment of a water balance the tissue water may not return to its former level so long as the hyperglycemia persists The same phenomenon may be observed when a severe but controlled diabetes is thrown out of control by a complication or insulin omission In such cases control of the diabetes may lead to the opposite phenomenon the intake of water exceeding the output and the body weight rising Similar fluctuations of weight may occur during the development and resolution of edema

WEAKNESS —Moderate degrees of fatigability may develop with hyperglycemia More marked weakness appears with undernutrition The extent of the weakness may parallel that of the undernutrition Peripheral neuritis and degenerative lesions in the spinal cord may also cause weakness often most marked in the lower extremities *The appearance of weakness in a diabetic who has not been weak before or an increase of weakness in one who has is a characteristic and constant early symptom of acid intoxication* The occurrence of this symptom should always lead to an examination of the urine with ferric chloride

PRURITUS —Generalized itching of the skin occurs more often in advanced cases with marked diuresis emaciation and dryness of the skin than in beginning diabetes It is not very common and usually disappears with control of the diabetes Itching of the genitalia and of the skin of adjacent parts is a much commoner symptom It is generally due to balanitis or vulvovaginitis or to dermatitis or both and is often the first indication of diabetes These affections of skin and mucous membranes which have been attributed to the irritating effects of sugar are rather of mycotic origin The mucous membranes become *reddened* swollen and covered with patches of fibrinous exudate The process may lead to phimosis in the male and in females at times to phlegmonous vulvitis or furunculosis of the labia When dermatitis occurs the parts chiefly affected are the groins the inner surfaces of the thighs the internates axillae and inframammary regions But lesions may appear elsewhere as between fingers and toes in the corners of the mouth etc The skin becomes reddened swollen and sometimes scaly In similar lesions in nondiabetics Finnerud states that of the yeasts or yeastlike fungi that may be responsible those most commonly found belong to the group of monilia (*Oidium albicans*) and that in cases without mucous membrane involve-

ment the cryptococcus appears to be the next most frequent offender Hesseltine reports the recovery of fungi in 18 out of 21 cases of vulvovaginitis in diabetics With control of the glycosuria the disorder usually disappears but sometimes persists and requires special treatment In such cases paintings with a saturated solution of pyoktanin blue (gentian violet) are probably of the most service whether the lesions are on the skin or the mucous membranes

CONSTIPATION —Beginning diabetes with marked glycosuria is often attended by constipation Whether it is due to nervous factors or to the diversion of water from the bowel it usually disappears with control of the diabetes and the establishment of a diet containing a normal proportion of vegetables and fruit

SOMNOLENCE —With hyperglycemia and glycosuria patients often complain of feeling drowsy or dozing after meals Perhaps this symptom is due to internal redistribution of water The possibility has also been suggested that glucose itself as an alcohol may exert some soporific effect *Somnolence is also a symptom of early acid intoxication*

DIMNESS OF VISION —Dimness of vision may be due to refractive changes caused by alteration of the water content of the eye and of the vitreous in particular The refraction may change rapidly with variations of the hyperglycemia glycosuria and diuresis but returns to its original status when the disturbing factors are eliminated In elderly subjects dimness of vision is frequently due to other causes such as cataracts disease of the retinal arteries—so called diabetic retinitis etc In such cases the diabetes itself may have little to do with the course of the symptom In the latter type of visual defects the lesions are found by examination

IMPOTENCE —This is a common symptom often observed in well nourished or obese individuals with mild diabetes after the third decade of life The sex power is said to return in some cases with disappearance of the glycosuria It is not necessarily associated with the absence of motile spermatozoa nor with testicular atrophy It is possibly an associated glandular dysfunction This view is supported by increasing evidence of pituitary dysfunction

SYMPTOMS REFERABLE TO THE NERVOUS SYSTEM —A great variety of nervous symptoms may occur in the course of a diabetes

LOSS OF THE PREPATELLAR TENDON REFLEX —According to Rosenstein Grube and Naunyn this appears in 20 to 30 per cent of cases De Renzi found the knee jerks normal in 2 weak in 10 and absent in 38 out of 50 cases The symptom is rare in young individuals Some improvement may follow adequate treatment of the diabetes Autopsies may reveal no morphologic changes in the peripheral nerves or spinal cord but degenerative lesions have been observed in the posterior columns Exaggeration of the knee jerks is not incompatible with diabetes

MUSCLE PAINS —Muscular weakness which is one of the classic symptoms of diabetes may be associated with aching or pains in the muscles with little or no tenderness on pressure and this is sometimes observed in the mildest cases suggesting a possible neuritic factor This symptom is to be distinguished from *muscular cramps* that cause severe pain and tender swellings These may also occur with mild diabetes and arteriosclerosis but are more often observed with severe glycosuria and polyuria Of the *neuralgias* those of the sciatic nerve and brachial plexus are the most common although any nerve may be involved A modern tendency is to consider these symptoms as manifestations of bursitis fibrositis osteo arthritis focal infections etc which doubtless contribute in many cases as does also the state of the arteries But true neuritis also occurs

PERFORATING ULCER similar to that seen in tabes spina bifida syringomyelia leprosy etc is relatively rare in diabetes It is not due to syphilis Its usual site is on the foot It has been reported in other locations also Its appearance in atypical sites and its healing in some cases have been said to distinguish it from *mal perforant* of tabes dorsalis *True polyneuritis* in diabetes gives rise to a great variety of manifestations not necessarily to be distinguished from those of polyneuritis in nondiabetics The name of diabetic *pseudotabes* is applied to a form of diabetic multiple neuritis with loss of the knee jerks ataxia and muscular weakness The pupils may be contracted and react sluggishly but there is no true Argyll

Robertson pupil The sluggishness of the pupil may be enhanced by sclerosis of the arteries of the iris In some cases degenerative lesions in the posterior columns have been found in conjunction with degenerative changes in the nerves

FURUNCULOSIS —Furunculosis may occur in any stage of diabetes and may be an indication of the disease But it is also common in nondiabetics The existence of an unbalanced diabetes implies a lowered rate of glucose burning in the various tissues including the skin and this may be associated with a diminished resistance to infection This factor may be corrected by suitable treatment of the diabetes Otherwise the pathogenesis course and treatment are those of furunculosis in general A run of boils is often due to repeated reinoculations of the skin so that apart from general measures it is important to isolate any discharging lesion When moist dressings are used a saturated solution of magnesium sulfate has many advantages Avitaminoses should be corrected

GANGRENE —The arterial disease that is characteristic results in thickening of the tunics and narrowing of the lumina of the arteries Occlusion of an artery leads to gangrene Although existent in variable degrees throughout the arterial system the disease is most marked in the lower extremities The blocking of a digital artery or a smaller cutaneous branch causing gangrene of a toe or a superficial area may often be handled conservatively Occlusion may be spontaneous or may be provoked by slight injury or infection It is frequently followed by secondary infection When a larger artery of the metatarsus occludes early amputation is indicated Owing to the fact that the anterior and posterior tibial and peroneal arteries and their branches and anastomoses are all commonly involved in the same general process it is usually preferable to amputate above the knee The state of the arteries that leads to gangrene is not appreciably changed by treatment directed at the diabetes It is often most marked in the mildest cases

DIABETIC XANTHOCHROMIA —Many patients with severe diabetes develop a yellow coloration of the skin a symptom described as xanthochromia The color varies in different cases from a light lemon to a reddish saffron or chrome yellow The staining is often deepest in the skin of the palms and soles The color is due to carotin which occurs in excess in the blood in these cases It is more commonly seen with undernutrition and disappears with control of the diabetes and the establishment of a normal diet. It is associated with an abnormality of the lipoid metabolism and according to Rabinowitch with that of cholesterol in particular

XANTHOMA DIABETICORUM —Diabetic xanthoma is also associated with abnormalities of the lipoid metabolism that may develop in the course of a diabetes and disappear with control of the latter condition The relation between diabetic xanthoma and that which occurs in nondiabetics has not been established

Symptoms of Acid Intoxication —The character and intensity of these symptoms depend in the main on the degree of depression of the alkali reserve and the sequence of symptoms on factors that determine its variation Thus the symptoms may appear insidiously or suddenly advance slowly or rapidly remain stationary for a longer or shorter time or recede depending on variations of the diet the insulin dosage the intake of base the severity of the diabetes and other factors that determine the alkali level With a steadily falling alkali reserve the following are the commonest early symptoms

1 *Weakness* when none has existed before or the accentuation of preexisting weakness

2 *Anorexia or Nausea or Nausea and Vomiting*

3 *Increased Frequency of Respiration*

4 *Dulling of the Sensorium*

5 *Cutaneous Flush*

6 *Acetone Odor on the Breath*

In the earliest stages any or all of these may be inconspicuous The respiration may not be increased except on exertion The color of the face may be hard to distinguish from that due to exposure to wind or sun The acetone odor may not be distinctive But unusual tiredness or willingness to rest and especially a dulling of the appetite symptoms of gastric hyperacidity anorexia or nausea in a diabetic should awaken suspicion In cases exhibiting these milder

symptoms the plasma CO_2 is usually between 20 and 40 volumes per cent

With deepening intoxication weakness progresses the respirations increase in frequency and depth The symptom *air hunger* makes its appearance Nausea and vomiting continue *Pains* may appear of a neuralgic or neuritis like character in one nerve or plexus or more often in several

Abdominal pain—usually epigastric—may be severe and simulate appendicitis or pancreatitis A *leukocytosis* is frequently found The count may rise to 25 000 and over However abdominal pain occurs only in a limited proportion of cases and pain in general is frequently absent Symptoms of *dehydration* are constant *Thirst* is incessant The skin lips tongue and fauces become dry the intra-ocular tension is diminished (soft eyeball) Dulling of the senses and of the mind progresses The patient is frequently somnolent Exceptions occur with urgent dyspnea the patient remaining alert and anxious as he struggles for air The plasma CO_2 is then between 10 and 25 as a general rule

With deep acid intoxication the stormier symptoms—nausea vomiting pain etc subside as the mind and senses become more dulled with developing coma Coma however is seldom so deep that the patient cannot be aroused enough to swallow until shortly before death The following is taken from Kussmaul s description of the comatose patient (1874) There is nothing to show that the air in its passage to and from the lungs has the slightest obstruction to overcome The chest expands freely in all directions The full inspirations are followed by just as full expirations There is no congestion of the veins of the neck no cyanosis These great respirations are further as a rule accelerated The contrast between the general weakness and the strength of the respiratory movements is one of the most striking features of the picture

The urine in coma commonly shows besides sugar acetoacetic acid etc a trace of albumin and many casts Fever is usually the sign of a complication or dehydration After acid production has been controlled the injury done to the tissues during the period of acidosis is not immediately repaired and if irreparable the patient may fail to recover consciousness after the acidosis is stopped or may recover consciousness and die of heart failure The plasma CO_2 is usually between 10 and 15 per cent

The longer an acid intoxication continues the more frequent is the occurrence of complications The prolonged effect of acid on the tissues frequently leads to *dilatation of the heart atony of the muscles of deglutition atony and dilatation of the stomach dilatation of colon anuria* etc

Clinical Course—The clinical course in the individual case is extremely variable There are cases with sudden onset and rapid progress which lead to coma within a few weeks unless active preventive steps are taken Such cases are commonest in childhood and youth A case may begin with all signs of severity and later assume the aspects of mildness or the reverse may occur an apparently mild case becoming severe Generally speaking in a child developing diabetes the major part of the tolerance will have been permanently lost within one to one and one half and in a youth within two to three years of the onset although careful treatment and unknown factors may result in the preservation of the tolerance for much longer periods As a general rule also the greater the age at which diabetes appears the slower will be its subsequent course But many exceptions must be noted Rarely and usually in subjects no longer young a definitely established and long standing diabetes severe enough to require insulin treatment may become mild or disappear temporarily or permanently Whereas many factors capable of affecting the course are known there are still unknown factors of high importance Joslin formerly stated that complete disappearance of a diabetes during life had not been proven in any of his cases and held to the view Once a diabetic always a diabetic Naunyn von Noorden and others believed that cases might recover The diabetes associated with disease of the pituitary is notable in this respect and I have seen cases of *apparent* recovery in the absence of *recognized* pituitary disease (Since the above was written I understand that such cases have also been observed in the Joslin Clinic)

In the section on Heredity we have re-

ferred to the phenomenon of *Anticipation* and suggested the possibility of considering the true course of diabetes as run in a family as distinguished from the individual case The suggestion implies that diabetes may appear in a given family in which it has not been known to occur before and run its course in a limited number of generations (as few as two most often three occasionally four and rarely more) When the disease begins in a given family it first affects persons in the forties, fifties or later, after a generation or two those in the twenties thirties or forties and finally in youth and childhood In accordance with this conception the old diabetic is usually a first generation case and a juvenile diabetic a second third, or fourth generation case and most often a third Well known differences in the course of diabetes in the old and young are *related to the age of the family disease* The old diabetic represents an earlier stage and a young diabetic a more advanced stage in the course of the disease

Clinical Types —The degree of impairment of the power of the body to dispose of glucose is commonly used as the basis for a classification of cases of diabetes as mild moderate or severe However mildness or *severity is not wholly a matter of degree* At the beginning of a diabetes destined to run a rapid course the degree may be slight but the type severe as shown by its progress An inherently mild type of diabetes is one of low or moderate degree manifesting relatively little tendency to progress The diabetes of elderly subjects is commonly of a mild type and pure diabetes in young subjects severe But low grade slowly progressive types of diabetes may occur in the young and even in slowly progressive cases time may determine a loss of tolerance equal to that which occurs more quickly in other cases

Diagnosis —The occurrence of characteristic symptoms such as thirst and polyuria with or without others and the finding of sugar in the urine leave little doubt of the diagnosis Problems arise when positive qualitative tests for sugar in the urine or unusually high blood sugar percentages are found more or less accidentally in the course of a general examination such as a health or insurance examination, or that of a patient whose principal symptoms are those of some other *condition* In such cases a study of the family history the physical type of the patient and of signs that are often associated with diabetes may afford clues of much importance A history of diabetes in the family the inheritance of physical characteristics that are often associated with diabetes such as unusual height stature or obesity, a family history of metabolic or endocrine abnormalities, which if not diabetic may be related to diabetes arteriosclerosis hypertension, renal glycosuria etc, are all suggestive However, proof that a subject is diabetic rests on the demonstration of the characteristic anomaly of the glucose metabolism This anomaly cannot be proved to exist prior to the appearance of glycosuria

Diagnosis of Glycosuria—This rests on *the demonstration of an abnormal quantity of a dextrorotatory fermentable reducing substance in the urine Qualitative Data* A definitely positive qualitative test with one of the commoner copper reagents indicates more than the usual concentration of reducing substance If after the urine has been fermented with yeast it no longer yields a positive test the reducing substance is probably *a sugar If the unfermented* specimen shows dextrorotation and if this disappears with fermentation the sugar is glucose as other dextrorotatory and fermentable reducing substances are not known to occur in human urine *Quantitative Data* As measured by the Folin Berglund method for the quantitative estimation of sugar in normal urine the total output of sugar (fermentable and nonfermentable) by adults on diets consisting of staple foods is commonly found between 0 3 and 0 9 Gm in twenty four hours Even when enough glucose is added to the diet to bring the total glucose supply *to 400 Gm the output is* commonly less than 1 Gm exceptionally 1 to 1.5 rarely 2 to 2 5 Gm The excretion of 1 5 Gm or more is therefore abnormal If a repetition of the determination after fermentation shows a fall of the figures (as to *0 2 to 0 4* Gm) the difference is probably due to glucose With slight sugar excretion the qualitative test may be negative and polariscope readings unsatisfactory In fasting the total sugar excretion is usually less than 0 4 Gm

in twenty four hours or 0 1 Gm per six hour period After a meal or the ingestion of glucose it rises The excretion of 0 4 Gm or more in six hours or of 0.2 Gm in three hours after a glucose feeding (of 100 Gm) is unusual and suggestive

Differential Diagnosis of Glycosurias—The glycosuria of diabetes responds in a characteristic way to diet changes and in sulin With rare exceptions it disappears with sufficient limitation of the diet (with or without insulin) When absent on a given diet (with or without insulin) a rising diet leads to its reappearance when the glucose supply exceeds a limit (any insulin dosage remaining the same) With diets rising above this limit it shows a *progressive* acceleration When glycosuria is present on a given diet it shows characteristic responses to insulin The glycosuria of true diabetes is associated with hyperglycemia In renal glycosuria and innocent glycosurias of pregnancy the blood sugar percentage remains as a rule within normal limits There is then no definable tolerance limit little or no *progressive* ac celeration of the sugar excretion with rising diets and 10 to 20 units of insulin have very little or no effect Thus in a typical case of renal glycosuria the excretion of sugar for three days on a constant diet calculated to introduce into the body 150 Gm of glu cose per day may average x Gm and on a similar isocaloric diet with a glucose equiva lent of 300 Gm the output may average $2x$ Gm or somewhat more the excretion representing the same or nearly the same percentage of the higher and lower glucose supplies In true diabetes once glycosuria has made its appearance the percentage ex cretion rises with even a moderate dietary increase In some types of inherently mild diabetes the tolerance limit is ill defined the response to insulin slight and the accelera tion of the glycosuria with rising diets less striking than that in purer forms Even so a sufficiently high insulin dosage will stop the glycosuria and with diets sufficiently low and high the difference in the percentage excretion is definite Glycosurias other than renal and pregnancy glycosurias whose inno cence is proved in the course of time by their clinical course may be associated with hyperglycemia and may respond to insulin doses But often the dose of insulin required to eliminate a few grams of sugar from the urine is greater than that which might be expected in a typical case of true diabetes and the acceleration of the glycosuria on rising diets is frequently less These consid erations may assist in the differentiation of nondiabetic and diabetic glycosurias *Blood Sugar Criteria* The fasting blood sugar level is usually found between 0 06 and 0 12 averaging 0 1 per cent A fasting blood sugar of 0 13 per cent is suggestive of some ab normality although not necessarily diabetes Most writers agree that a fasting value of 0 17 per cent or over is definitely abnormal and usually due to diabetes in which case there should be no difficulty in demonstrat ing the passage of more than a normal amount of sugar in the urine either in fasting or after a meal The elevation after a meal or a dose of glucose is said to be normal when the peak attained is 0 17 per cent or less and the total duration less than two hours The peak level is said to be less significant than a prolongation of more than two hours

Treatment—We may consider treatment under the following headings

1 *Acidosis*

(*A*) In the early stages before ketosis has resulted in enough depletion of the alkali reserve to cause clinical symptoms (symptoms of acid intoxication)

(*B*) In the intermediate stages in which the depletion of the alkali reserve is enough to cause symptoms of mild or beginning intoxication (p 614)

(*C*) In the more advanced stages with symptoms of deep intoxication pre-coma or coma (p 615)

2 *Surgical and Medical Complications*

3 *General Treatment*

Acidosis—(*A*) Without Symptoms of Intoxication—The presence of aceto acetic acid in the urine implies the presence of an even greater quantity of β hydroxy butyric acid and a continuing drain on the alkali reserve It should be checked at once before it leads to intoxication In checking a ketosis it is desirable to follow a more or less stereotyped orderly plan that a pa tient can learn so that he may apply it him self on future occasions and to use the opportunity for a demonstration The follow ing plan has been proved reliable

Emergency Program —Divide the twenty-four hours into 4 six hour quarters Let the periods begin and end at 6 A M and 12 A M, and 6 P M and 12 P M (or at 7 A M, 1 P M 7 P M 1 A M) At the end of each period empty the bladder test the urine for sugar and acid give a dose of insulin and a *standard feeding* On discovering ketosis *in the absence of symptoms* start the procedure at the beginning of the first regular period thereafter

A *standard feeding* may consist of 400 Gm (2 glasses or a pint) of milk (or 2 parts milk to 1 of cream) or 300 Gm orange juice or equivalent (28 to 30 Gm sugar) The exact quantity is nonessential but it should be the same in each period It is not necessary to provide a maintenance ration

The Initial Insulin Dose —With a patient who has not been taking insulin 5 to 10 units with one who has, a quarter of the regular twenty four hourly dose is given *If the patient has been using protamine insulin* (alone or in combination with regular insulin) it is better not to disturb the protamine insulin The usual dose of protamine insulin may be given daily at the regular hour *in addition to* the doses of regular insulin each six hours In case acid should be discovered for the first time before breakfast the emergency program need not be begun unless acid is still present before the noon meal

The Second Insulin Dose —When at the end of the first period the urine still shows sugar and a positive ferric chloride reaction make the second dose 5 units more than the first

Following Doses —So long as acid persists at the end of a period make the next dose 5 units more than the last When acid is absent but sugar persists make the next dose the same as the one preceding With acid absent and sugar fading make it 5 units less Sugar free urine or an insulin reaction before the end of a period may call for a reduction of more than 5 units When the urine has remained nearly sugar free and the patient free of insulin reactions for two successive periods on the same dose of insulin take steps toward resuming a normal schedule

Discontinuing the Emergency Program —This procedure will vary in different cases depending on the height of the insulin dosage the presence or absence of complication, *etc* *In more difficult* cases the following steps may be taken (1) replace the standard feeding morning noon and evening with *equivalent mixed meals composed of foods* that will appear in the final breakfast, luncheon and dinner (Example orange juice 100 Gm, egg 50 Gm bread 20 Gm. butter 5 Gm and cream 25 Gm, roughly equivalent in C P and F to 400 Gm milk, *may serve as a breakfast substitute* and so on) (2) At midnight drop the standard feeding and give half the calculated insulin dose (3) *Build up the breakfast* luncheon and dinner, meanwhile retaining a dose of insulin before each meal (4) Convert the midnight into a bedtime dose reduce it as fast as conditions permit and adjust and condense the remaining doses

(*B*) WITH SYMPTOMS OR MILD OR BEGINNING INTOXICATION —In the presence of such symptoms (p 614) the treatment may be conducted by six hour periods as in cases with ketosis without toxic symptoms (*A*) but with the following variations

1 Begin treatment at once regardless of hours

2 Omit the feedings until the toxic symptoms disappear

3 Make the first dose of insulin decisive so that symptoms disappear within the first six hours

A decisive dose may be 1 unit per kilogram of body weight Err on the side of giving more than required rather than too little In the presence of symptoms there need be no fear of insulin reactions There should be fear of coma When the symptoms have been stopped including the nausea and the urine obtained at short intervals shows little sugar there may then be danger of a reaction but it is easily preventable by oral doses of 50 to 100 Gm of orange juice hourly or enough to keep sugar passing into the urine Even with vomiting from other causes besides acidosis if a pool of sugar is kept in the stomach enough will usually pass through the pylorus to prevent reactions (*e g* a teaspoonful of 50 to 100 per cent sugar in tea or water every half hour and after each emesis) When symptoms are gone proceed as in (4) In this case also if the patient has been taking

protamine insulin the usual dose can be given daily at the regular hour in addition to the one of regular insulin given at that hour in the emergency schedule

(C) More Advanced Stages —*Precoma Coma*—As in milder cases treatment may be conducted by six hour periods

First Period Management—1 *Give a maximum dose of insulin Establish at once as much insulin action as can be produced by any dose* Two units per kilogram of body weight will probably accomplish as much as more in the first four to five hours but the action curve having reached a peak will have begun to decline by the end of the fifth and be waning definitely in the last hour of the period So in critical cases the dose should be repeated in the middle of the period three hours after the original dose

2 *See that the patient is kept warm* Warm blankets are safest Many patients are burned with hot water bottles

3 *A cleansing enema* to prepare the bowel for the retention of water

4 *A retention enema* of tap water or normal salt solution which may have a volume of 5 cc per kilogram of body weight These cases are always dehydrated by sugar and acid The bowel is an invaluable vehicle for water It should not be dilated by attempts to give too much at once nor irritated by such substances as bicarbonate or sugar Experience has shown that 5 cc per kilogram of warm saline or water will be retained very often once in six hours for a number of periods Attempts to give more may defeat their purpose

5 *Aspirate the stomach contents* to remove possible accumulations of acid and to detect dilatation or atony if present

6 Conditions permitting *give water by mouth* at the rate of 1½ cc per kilogram per hour (about 100 cc or half a glass per 70 Kg) If there is doubt of the motor power of the stomach aspirate after three to four hours and in case of retention allow the stomach to rest and try again later With no retention a more rapid rate may be tried In simple cases it may even be doubled With 1½ cc per hour for six hours by mouth and 5 cc per six hours by bowel the total intake for the period is 14 cc per kilogram or about 1 liter for a patient weighing 70 Kg This rate of water supply continued usually suffices to overcome symptoms of dehydration in two to three periods which is rapid enough for most practical purposes It is not necessary to restore a high normal hydration for the relief of symptoms In extreme dehydration produced by intravenous injections of glucose in dogs the quantity of water required to relieve symptoms may be 3 per cent or less and for full rehydration 5 per cent or less of the body weight There may be no objection to hastening the process of rehydration by giving an extra liter of water in the first period by mouth if conditions permit or otherwise by hypodermoclysis but it is not imperative and extremes are harmful

When the stomach or bowel or both are incompetent part or all of the water must be given parenterally in the form of a normal saline solution by hypodermoclysis For this purpose and especially in later periods the subcutaneous drip at a measured rate is advantageous There is no objection to venoclysis if *slowly* given

7 If the heart needs support caffeine, digitalis or for quick stimulation camphor in oil (repeated at short intervals if necessary) may be recommended

In not too severe cases a fall of the respiration and general improvement may occur in three to five hours from the beginning of treatment but a case would not be severe if symptoms were gone by the end of the period not to mention ketosis and glycosuria In advanced cases therefore insulin reactions are out of the question in the first six hours

Second Period Management—Symptoms continuing even if improvement has already begun it is unsafe to diminish the insulin dosage At the beginning of the period give a maximum dose and maintain the rate of water administration In this period however there will be the possibility of an insulin reaction To avoid this the urine should be obtained at one to two hour intervals (by a retaining catheter if necessary) and examined for sugar and acetoacetic acid With fading ferric chloride and sugar reactions enough sugar should be administered every hour to keep a moderate amount passing into the urine When oral administrations are possible 50 to 100 Gm of orange juice hourly (5 to 10 Gm sugar) will com

monly do otherwise 50 to 100 Gm of 10 per cent aqueous glucose solution hourly by vein or subcutaneous drip When in the middle of the period symptoms and ketosis have disappeared no more insulin need be given until the end of the period If in the middle of the period symptoms persist continue the insulin as in the preceding period If by the end of the period there is no definite improvement of the general condition the prognosis should be guarded *Oliguria* or *anuria* in the first period may be due very largely to dehydration If it persists or appears in the second period, when enough water has been given for urine formation it may be necessary to mobilize water held in the tissues in colloidal union For this purpose 300 cc of 1 4 per cent sodium chloride *solution by bowel (in place of normal saline)* or by stomach tube or intravenously if *necessary* will often suffice If the first dose fails a second may be given More concentrated solutions intravenously given are recommended by some writers (*e g* 50 cc of 10 per cent salt solution) With too concentrated solutions the possibility of thrombosis should be borne in mind There may be some advantage in a supplemental dose of 10 to 15 Gm of sodium bicarbonate given orally or by stomach tube

THE USE OF ALKALI IN COMA —The stopping of abnormal acid production by the administration of adequate doses of insulin stops the depletion of the alkali reserve of the plasma lymph and permits of its rapid restoration by base derived from endogenous sources This restoration begins at once with the fall of the rate of acid production and is usually complete within a short time when acid production has fallen to normal There is thus ordinarily no necessity for the administration of *alkali* for the purpose of restoring the *alkali reserve* so long as the total base reserve suffices for this The administration of an adequate quantity of insulin is the measure of greatest primary importance Next in importance is the restoration of the water balance When the administration of alkali is unnecessary and when it diverts attention from prime essentials or interferes with their execution it should be discouraged *Administrations of alkali by the bowel* are objectionable because they cause irritation of the bowel which renders it useless during the emergency as a channel for the administration of water, and because the quantity of alkali that can be so given is very limited Attempts to give 300 cc of a 3 per cent solution (9 Gm) of sodium bicarbonate in six hours by bowel usually result in nonretention In the presence of a *continuing* acid production even at the moderate rate of 104 Gm in twenty four hours or 26 Gm in six hours the quantity of soda required for neutralization would be 21 Gm per six hour period *Intravenous alkali administrations* are even more objectionable The heart in coma is seriously weakened and may be mechanically overtaxed by the too rapid injection of a large volume of any solution If intravenous injections are made at all they should be given evenly and very *slowly Perhaps 100 cc per hour might* be taken empirically as a limit to be exceeded only with the greatest caution The strength of a bicarbonate solution for intravenous injections should hardly exceed 3 to 5 per cent. With these limitations the quantities of bicarbonate that may safely be given are too small to justify the procedure Thus generally speaking, alkali therapy is non essential and in practice often injurious

But the following facts may be recalled In 1878 Walther published his study of the effects of acid on the animal body which established the principles on which the modern conception of acidosis is founded—that of the alkaline reserve of the blood its existence in the form of bicarbonates the percentage of CO_2 in the blood as a measure of the alkaline reserve etc Walther gave rabbits lethal doses of mineral acids and when symptoms of poisoning had made their appearance gave calculated doses of alkali to some with the result that they promptly recovered while untreated animals died in coma Thus after the administration of a sufficient dose of acid death resulted *even when no more acid was given* but could still have been averted by alkali therapy Before the advent of insulin it was frequently possible when fasting or undernutrition failed to abolish the symptoms of acid intoxication in diabetics by the administration of sufficient quantities of sodium bicarbonate by mouth or stomach tube The quantities given were necessarily large 50 to 100 Gm or more in the course of twelve hours *de*

pending upon the rate of acid production The administration of a sufficient dose of insulin does stop acid production but the action is not instantaneous After the beginning of insulin treatment acid production may be declining but still continuing during a period of six to twelve hours or even longer The effectiveness of insulin is greatly reduced in high acidosis And when treatment has been begun too late patients still die It would appear that when a patient has received a lethal dose of acid death will result even if acid production is stopped The question may be considered as to whether some cases which have or will have received a lethal dose of acid before acid production has been stopped by insulin may not still be saved like Walther s rabbits by alkali treatment that will hasten the restoration of the acid base balance

Management in the Presence of Intercurrent Disease—An intercurrent illness such as a common cold an acute respiratory tract infection a tonsillitis sinusitis or appendicitis an injury a major or minor surgical operation indeed any condition capable of affecting the general health may lower the tolerance of a diabetic or if insulin is used increase the requirement In the presence of any such factor it is therefore desirable to examine the urine at frequent intervals *e g* before or after meals and at bedtime If the condition proves to be innocent nothing more is required If sugar appears when absent before but without acetoacetic acid requisite adjustments may be made If both sugar and acid appear one may proceed as for acidosis without symptoms and continue management by six hour periods as long as conditions may require

Management of Surgical Complications—When the diabetes is under control and an operation is contemplated one may expect that the operation will lower the tolerance or increase the preoperative insulin requirement although with mild enough cases it may not do so When conditions permit it is a good plan to establish a six hour program for three or four periods before the operation and to determine the insulin requirement if any per period on a standard feeding and also fasting for although the postoperative requirement will not be the same it will not be less With cases requiring insulin before operation it is desirable when possible to schedule the operation for the second half of a period so that a standard feeding (or its equivalent in sugar or cereal gruel) may have had time to pass through the pylorus and so that the period may close after the operation The insulin requirement for the first postoperative six hour period may be anything over the preoperative requirement One may start with the latter and closely observe the urine and blood giving an extra dose in the middle of the period if indicated As nausea etc will interfere with feedings the patient may fast or one may administer the usual six hour glucose supply in the form of 5 per cent glucose solution by vein or the subcutaneous drip When prior to the operation the diabetes is already out of control as it may be for example in a case of appendicitis the operation should preferably be deferred until control is established or at least until acidosis is stopped An urgent operation need not be deferred for glycosuria alone as control may be gained in the postoperative periods But acidosis enormously increases risks and can usually be stopped in six to twelve hours

General Treatment—Cure of the disease is beyond reach at present The object of treatment is to maintain life and reduce disability to a minimum—physical mental emotional and economic The patient must be established on a diet that provides the essentials for physical health and gives as much satisfaction as possible Bizarre diets that unduly limit variety are difficult to follow for long periods of time The character and magnitude will necessarily differ with different patients The artisan whose ability to earn his living depends on his physical strength must have food to sustain him or become dependent The scholar artist or musician may do with less From the purely physical standpoint a diabetic does better as a general rule if he is kept spare and a trifle under rather than overnourished

The *education of the patient* is of the utmost importance as it devolves upon him to maintain the advantages gained by an adjustment of his diet insulin etc Systematic education of the patient in all that pertains to the maintenance of the life and health of a diabetic and a systematic follow up service are essential parts of the manage

ment Of vital importance to a diabetic is a knowledge of when to be particularly on the lookout for acidosis, how to detect it and what to do if he finds it as this has to do with the preservation of life

Caloric Requirements—These vary with age sex weight height surface physical activity, state of nutrition and other factors For normal subjects the average requirement may be determined from charts and tables prepared for the purpose such as the following of DuBois and Du Bois and Aub The chart (Fig 60) is based *on the formula* Surface Area (sq cm) = $wt^{0.425} \times ht^{0.725} \times 71.84$

Suppose the patient to be a man thirty five years of age whose weight is 70 Kg and whose height is 170 cm (69 inches) In Figure 60 it will be *found that a horizontal* projection of the point on the height column at 170 cm will meet a perpendicular projection of the 70 Kg point on the base line at approximately 1.8 on the diagonal This means that the surface area of the individual is 1 8 square meters Since Table 1 shows that the hourly caloric requirement of a man between thirty and forty years of age is 39.5 per square meter of surface area this patient will require 1 8 × 39.5 × 24 (hours) or 1730 calories daily under basal or minimal conditions (to maintain his weight)

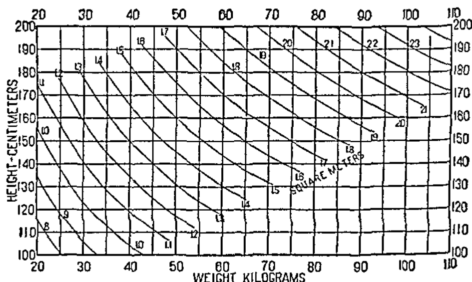

Fig 60—Chart for determining surface area of man in square meters from weight in kilograms (wt) and height in centimeters (ht) according to the formula area (sq cm) = $wt^{0.425} \times ht^{0.725} \times 71.84$ (DuBois)

Having determined the surface area of a patient from the height and weight by means of the chart the average caloric requirement may be read from Table 1

Table 1*—The Average Caloric Requirements per Square Meter of Body Surface in Both Sexes for Different Periods of Life

Age	Calories per square meter per hour Male	Female
14–16	46	43
16–18	43	40
18–20	41	38
20–30	39.5	37
30–40	39.5	36 5
40–50	38.5	36
50–60	37.5	35
60–70	36 5	34
70–80	35 5	33

* Taken from page 122 Aub and DuBois Carnegie Reprint

In actual practice on individual cases a diet composed on the basis of averages may prove to be higher or lower than *required* for the maintenance of a given weight in which case it may be adjusted as requisite *The body weight as observed* over a period of time long enough to avoid confusion resulting from fluctuations of the body content of water is the most practical guide When feasible to do so the plan for maintaining the body weight slightly below the average for normal subjects may be recommended For rapid estimation *of caloric* requirements one may assume that at bed rest 25 calories per kilo are needed at light work 30 at heavy work 35 and upward

PROTEIN REQUIREMENTS —It is possible under suitable conditions to maintain nitrogen equilibrium with quantities of protein as low as or lower than 0 6 Gm per kilo of weight in twenty four hours The tolerance of a patient is often higher or his requirement of insulin lower when the protein intake is kept at a low level However, other factors remaining the same differences observed on diets containing 0.5 and 1 Gm per kilo are seldom significant There is little to be gained and something to be lost by reducing the protein to the lowest possible limits If the protein is between 0 75 and 1.25 Gm per kilo for adults theoretic and practical requirements are met Growing children need 2 to 3 Gm per kilogram

CARBOHYDRATE AND FAT REQUIREMENTS —Having fixed the total and protein calories the balance must be divided between carbohydrate and fat The relative proportions that are most advantageous have been the subject of much discussion In this connection it may be recalled that the effects of given proportions are influenced by the total magnitude of the diet Thus a diet consisting wholly of 100 Gm of fat or carbohydrate would not be high in either component In diets of the type associated with the names of Petren in Sweden and Newburgh and Marsh in this country the preponderance of the nonprotein calories have been made up in fat (as much as 95 per cent in one of Newburgh s diets) On the other hand in the diets employed in the older cures a much higher percentage of the total calories appears in the form of carbohydrate *e g* Donkin s milk cure Mosse s potato cure During s rice cure von Noorden s oatmeal cure The same principle is embodied in the cereal diets of Falta Salamon Porges *et al* and in the high carbohydrate diets employed in this country by Geyelin Sansum Rabinowitch and others In milk containing C 5 P 3 F 4 per cent the C F ratio is 1.25 1 and in human milk 2 1 or higher in skimmed milk 8 or 10 1 In the original von Noorden oatmeal diet the fat sometimes equalled and sometimes exceeded the carbohydrate C F ratios of anywhere from 2 to 8 1 have been used in some of the high carbohydrate diets Diets containing a normal *quantity* of carbohydrates are generally liked by patients better than diets too low in this class of foods But excellent results can be obtained with various types of diet

Procedure in Establishing Diets—The choice of procedures is made on the basis of one s estimate of the severity of the case In relatively mild cases a diet designed for permanent use may be given at once and the results observed for a day or two If the sugar in the urine does not subside promptly one may hasten the process either by giving a lower diet or by using a small dose of insulin before each meal and increasing as requisite With severe glycosuria it may be well to begin with a maintenance diet In cases with heavy glycosuria the writer often begins with the emergency program described above for 2 reasons (*a*) to educate the patient in the use of the method against future needs and (*b*) to insure desugarization within twenty four hours

Insulin and Its Use—INSULIN AS A PROTEIN—The ordinary market preparations referred to as regular or 'standard insulin are purified extracts of the hydrochloride Since Abel s separation of insulin in crystalline form and Sahyun s development of a commercial method *crystalline zinc insulin* has become available on the market and bids fair to replace the hydrochloride extracts The injection of 10 to 20 units of the hydrochloride or of the crystalline zinc insulin results in an action which reaches its peak in three to four hours begins to decline in the fifth hour and has a total duration of eight to ten hours (in average conditions) With the use of such preparations alone any patient requiring more than 20 to 30 units per day will usually have to be given repeated doses To eliminate the disadvantage of multiple doses various methods have been adopted to retard the absorption or liberation of insulin by combining it with other substances such as oil cholesterol protamine histone globin arginine and others The most widely used are preparations of protamine zinc insulin The effects of standard preparations are slow in onset and relatively weak until reinforced by repeated overlapping doses but slow to disappear A single dose of 20 units of protamine insulin may have an action lasting 30 hours But after patients have received large doses daily for days or weeks effects

may be observed for several days after discontinuance The effects of a single moderate dose begin slowly, rise gradually attain a maximum between eight and twelve hours later and then gradually decline So if a single dose is given before breakfast the greatest effect is commonly between 4 and 8 P M The ideal curve would be one rising rapidly enough to cover breakfast lunch and dinner and falling rapidly enough to avoid insulin reactions between bedtime and breakfast without the necessity of a bedtime feeding Various attempts have been made to accomplish such curves Some dozens of combinations have been described Graham, Wilder and associates Colwell and associates have had considerable success with mixtures of protamine and hydrochloride or zinc crystalline insulin In cases requiring more than a limited dose per day one may use either separate doses of protamine and free insulin or such a mixture The mixture of three parts of standard or crystalline to one of protamine insulin recommended by Colwell, Izzo and Stryker has been used increasingly in the writer s clinic in the course of the past year For a full discussion of this subject with accurately plotted action curves see Colwell *et al* (Ref)

The method of administration favored in the writer s clinic a year ago was that of giving as much protamine insulin before breakfast as might be required to keep the urine sugar free or nearly so in the fasting quarter between midnight and morning (but not enough to cause insulin reactions in that period) If that quantity of protamine insulin given in the morning failed to control glycosuria by day as would be the case especially after breakfast and to a lesser extent after dinner at night in more advanced cases it was supplemented by a dose of regular insulin before breakfast and occasionally by a small dose of regular insulin before the evening meal although the latter was usually not required With patients adjusted on such a regime it was often found that the ratio of protamine to regular insulin was between 2 and 3 1 Latterly, as stated, we have tended to use single A M doses of 3 1 mixtures in many cases

For the handling of emergencies the quicker acting regular (or crystalline zinc) insulin is superior to protamine insulin (or equivalent) and it is better to avoid the possible confusion that may result from using the two together The full effects resulting from a change of the dose of protamine insulin will not be registered within twenty four hours whereas the full effect of a dose of regular insulin is obtained within ten to twelve hours so that in rapidly changing conditions it is preferable to use the more adjustable form

Hypoglycemic Reactions—Insulin Reactions—The commonest symptoms of a mild reactions are those felt with great hunger, weakness faintness pallor, tremor nervousness sweating those of more marked reactions—emotional symptoms laughing crying excitement, fright diplopia confusion disorientation or amnesia of severe reactions—muscular spasm and narcolepsy The pulse is commonly elevated and in the unconscious state the pupils are dilated In exceptional cases mono or hemiplegias appear and clear with the passing of the other manifestations Delay in recovery has been observed for days or months In uncomplicated cases death very rarely, if ever occurs The blood sugar percentage during a reaction may range from 0 09 downward to 0 02 or lower The degree of the depression varies in different cases and there is no exact correspondence with the symptomatology This is due partly to varying relations between the blood sugar concentration and the total body content of glucose and partly no doubt to other factors The time of a reaction is most commonly three to four hours after a dose of regular insulin followed by a meal as the action of insulin continues in the postabsorptive period Thus after a morning dose and breakfast a reaction may occur between 10 and 12 A M or 1 P M., and after an evening dose and dinner, between 9 and 12 P M After a large morning dose sufficiently covered by breakfast and lunch a reaction may occur in the late afternoon between 3 and 6 They are rarely belated more than eight hours with regular insulin After a dose not followed by food a reaction is possible within an hour After protamine insulin a dose given in the morning may cause a reaction in the afternoon or after midnight or before breakfast the following day Such reactions are apt to develop more slowly and when stopped may

recur in an hour or two Exercise or exertion may hasten or determine an insulin reaction by increasing the total consumption of sugar and the quantity burned per unit of insulin Mild insulin reactions disappear quickly after the ingestion of sugar orange juice or equivalents *With severe reactions in which the patient is not sufficiently conscious to swallow voluntarily attempts to administer fluids by mouth are best avoided for fear of aspiration and possible pneumonia* The subcutaneous injection of adrenalin hydrochloride 1 1000 (obtainable in ampules of 1 cc) will often restore consciousness within a few moments and may then be followed by sugar or orange juice given by mouth The dose of adrenalin may be for a child 0.3 to 0.5 cc for an adult 0.5 to 1 cc Its effectiveness depends on the mobilization of glucose from glycogen Cases in which the latter is too greatly depleted require intravenous injections of glucose

Spontaneous hypoglycemic symptoms appear in some cases of diabetes when no insulin has been given See section on Spontaneous Hypoglycemia

SPONTANEOUS HYPOGLYCEMIA

Definition—The term spontaneous hypoglycemia is here used in the purely descriptive sense to denote clinical pictures distinguished by symptoms of hypoglycemia and low normal or subnormal blood sugar levels The classification includes cases in which the hypoglycemia is due to excessive insulin production (*hyperinsulinism*) and others that arise from other causes

History.—The discovery of insulin (1921-22) led directly to knowledge of the symptoms that may accompany hypoglycemia The spontaneous occurrence of similar symptoms in 5 clinical cases in association with hypoglycemia was reported by Harris in January 1924 Harris considered the hypoglycemia to be due to excessive insulin secretion and in a series of papers developed the conception of *hyperinsulinism* as a disease entity as definite as the opposite condition *hypoinsulinism* or diabetes In 1927 Wilder and associates reported a case in which exploration revealed a metastasizing islet-cell carcinoma and in which insulin was recovered from the tumor tissue A few months later Finney and Finney explored a case in which the pancreas presented a normal appearance and in which partial resection was without definite benefit. In 1930-1931 Derick, Carr Evarts Graham and associates reported cases with islet-cell adenomas that were successfully removed with cure of the symptoms In the fall of 1934 there were reported in the literature 19 laparotomized cases All of these reports were by American authors In the meantime some hundreds of unexplored cases with varying degrees of hypoglycemia and a great diversity of symptoms were reported or cited here and abroad as cases of *hyperinsulinism*. The term *dysinsulinism* was proposed by Harris to describe cases exhibiting both hyperglycemia and hypoglycemia at different times

Etiology—The etiology may differ in different cases In a large proportion we are dealing with inborn defects of the sympathetic autonomic endocrine system of the same general order as those involved in other constitutional diseases of unknown cau e (diabetes migraine peptic ulcer gout and so on) In cases of true hyperinsulinism that happen to be associated with islet adenomas or carcinomas the etiology is no clearer than that of new growths in other parts Of other cases associated with hepatic dysfunction a fraction are due to acquired diseases (intoxications infections affecting the liver) but the majority as

stated are inborn defects *Excessive or unusual intakes of food and especially sweets* have often preceded the onset of symptoms These and *fatigue* are commonly recognized as provocative factors

Morbid Anatomy —To the end of September, 1939, there were reports in the literature of 62 cases that had been surgically explored or examined postmortem Islet cell tumors were found in 23 hypertrophy of the islets in 5, pancreatitis or unknown pathology in 3 The pancreas was normal in 31 A large proportion of the tumors were adenomas Some having the appearance of carcinoma on histologic examination have been encapsulated and nonrecurrent A minority were proved to be carcinomas Among the 200 cases of the milder types reported by Cammidge there was evidence of organic disease of the liver or hepatic dysfunction in a considerable number Harris refers to pancreatitis in association with gallstones or peptic ulcer

Lesions reported by various writers to November, 1940, are indicated in the following tabulation by Conn (For literature references see original)

I Organic—recognizable anatomic lesion
- (a) Hyperinsulinism
  1. Pancreatic island cell carcinoma
  2. Pancreatic island cell adenoma
  3. Generalized hypertrophy and hyperplasia of islands of Langerhans
- (b) Hepatic disease
  1. Ascending infectious cholangiolitis
  2. Toxic hepatitis
  3. Diffuse carcinomatosis
  4. Fatty degeneration "Fatty metamorphosis"
  5. Glycogenosis (von Gierke's disease)
- (c) Pituitary hypofunction (anterior lobe)
  1. Destructive lesions (chromophobe tumors cysts and so on)
  2. Atrophy and degeneration (Simmonds disease)
  3. Thyroid hypofunction (secondary to pituitary hypofunction?)
- (d) Adrenal hypofunction (cortex)
  1. Idiopathic cortical atrophy
  2. Destructive infectious granulomas
  3. *Destructive neoplasms*
- (e) Central nervous system lesions (lesions of brain and brain stem said to interfere with nervous control of blood sugar)

II Functional—no recognized anatomic lesion
- (a) Hyperinsulinism (autonomic nervous system imbalance?)
- (b) Renal glycosuria (severe degrees of low renal threshold for dextrose)
- (c) Severe continuous muscular work
- (d) Pregnancy and lactation

Physiology —The maintenance of normal blood sugar levels depends on the balance of many factors The influence of any single factor is necessarily relative to that of others Whereas, all other factors remaining the same, a rise or fall of insulin secretion may account for a hypoglycemia or hyperglycemia it does not follow that in pathologic conditions all other factors *are* the same Hypoglycemia can be produced in animals by the administration of insulin But it can also be produced in the absence of insulin by hepatectomy (Mann), hypophysectomy (Houssay), or adrenalectomy (Long and Lukens) So in the interpretation of hyperglycemias or hypoglycemias observed in the clinic it is necessary to consider other factors besides insulin secretion The power of the body to maintain normal blood sugar levels depends to a large extent on the liver Whereas the blood sugar regulating function of the liver is affected by elements (hormones etc) from other organs the liver itself is essential for blood sugar regulation In cases of spontaneous hypoglycemia with islet hypertrophy or islet tumors it might seem not improbable that we are dealing with actual *hyperinsulinism* In the milder cases it is necessary to consider other factors Those cases that exhibit quick oscillations from hyperglycemia to hypoglycemia referred to as cases of *dysinsulinism* and which might better be described as *poikiloglycemia* suggest disorders of the blood sugar *regulating* mechanism.

Symptoms —Those of insulinogenic hypoglycemia are discussed in the chapter on diabetes Harris distinguishes the following types

Mild Type —With spells of hunger weakness anxiety pallor especially about the lips sweating and trembling These spells occur at night or before breakfast luncheon or dinner or when the stomach is empty They disappear in a few minutes after the ingestion of sugar

Moderately Severe Type —With profuse sweating prostration more marked anxiety mental lapses periods of unconsciousness and spasms of isolated groups of muscles Attacks of this type may closely resemble *petit mal* but they are always relieved by the ingestion of sugar

Severe Type —With recurring attacks of

unconsciousness convulsion narcolepsy, associated perhaps with major hysteria or actual psychosis these attacks may resemble *grand mal* epileptic seizures

Abdominal Pain—Cramplike abdominal pain had led to cholecystectomy and appendectomy in cases of pancreatic adenoma described by Evarts Graham and others Harris speaks of 3 cases with pain in the midportion and upper left quadrant The pain disappears with relief of hypoglycemia Occurring at times when the stomach is empty and being relieved by food it is easily confused with gastric or duodenal ulcer

In the milder cases the clinical course is extremely variable In the more severe cases it may be rapidly progressive To control the symptoms it may be necessary to give feedings at intervals as frequent as every two hours The frequent feedings and interruptions of sleep may eventually lead to nonretention of food and require the use of parenteral injections Failure to control the hypoglycemia may result in death

Diagnosis—The diagnosis of hypoglycemia rests on the clinical history of recurring attacks coming on at hours of the day when the stomach is empty and relieved by the administration of sugar The demonstration of hypoglycemia confirms the diagnosis However when symptoms are not relieved by the ingestion of sugar even though the blood sugar is below the norm the question arises as to whether the low blood sugar level is actually responsible for the symptoms or not In cases of true hyperinsulinism relief from the ingestion of carbohydrate is definite and constant

'One fasting blood sugar determination or one glucose tolerance test is not always sufficient because there seem to be periods when the patient with hyperinsulinism will show normal readings The element of mental and physical fatigue affects blood sugar levels and in making tests the ambulatory patient should not be permitted to lie down The glucose tolerance test should be carried out for six full hours because in some cases the blood sugar levels may remain normal for the first four hours and fall to very low levels in the fifth and sixth hours (Harris) It has been shown by Conn that a patient on a low carbohydrate diet may fail to show a characteristic blood sugar curve but does so on a high carbohydrate diet and proposes the use of a standard high carbohydrate diet in preparation for a tolerance test

The characteristic blood sugar curve shows an unusually low or a normal peak and subsequent depression below that observed in normal cases

Treatment—In the course of attacks the treatment is that of insulin reactions (p 624) It should be noted however that the administration of sugar is very prone to be followed by even greater depressions of the blood sugar level than existed before and may lead to the production of further attacks In cases that have been sufficiently mild to permit Waters Sweeney Harris and others have reported favorable results from the use of low carbohydrate high fat diets The diets described have contained approximately 1.25 to 2 Gm C 2 to 2.3 Gm F and 1 Gm P per kilo per day (or about 20 to 140 Gm C 70 Gm P and 140 to 160 Gm F for the average patient) These diets are divided in 5 to 8 feedings But in the more severe cases it is impossible to adhere to diets of this type and more sugar must be given to prevent convulsions In certain mild cases the author has observed beneficial results from the use of injections of APL or insufflations of powdered anterior lobe (1 Gr t i d) Ephedrine is at best but mildly effective Epinephrine (1 mg b i d) may prevent attacks in milder cases Theoretically a diabetogenic extract of the anterior pituitary or of the adrenal cortex (Compound E Kendall) should be effective but available preparations of the adrenal cortex or anterior lobe that are sufficiently pure for clinical use have little diabetogenic effect In cases with severe recurring attacks it is necessary to institute frequent feedings at whatever intervals may be required In very severe cases the amount and number of feedings required to avoid convulsions may be more than the patient can take and retain and it is then necessary to use subcutaneous or intravenous glucose injections

In the more severe cases surgical measures must be considered When the exploration reveals a pancreatic tumor it should be removed When the pancreas appears normal partial resections have failed to give satisfactory results Subtotal resection as first

done by Graham, has resulted in cure in a number of cases In 1940 the literature contained reports of 10 cases subjected to subtotal resection of which 5 were cured, 2 improved and 3 unimproved In 3 of the cases there was islet hypertrophy while the pancreas was normal in the other 7 Of 17 cases in which tumors were removed 8 were cured 1 improved 3 not improved and 5 died as the result of the operation Many more had been reported at the end of 1942 In those cases that are associated with surgical conditions of the liver gallbladder or biliary tract relief of those conditions may result in improvement of the hypoglycemia

DIABETES INSIPIDUS

Definition—*Diabetes insipidus* is a chronic disease characterized by the passage of a large amount of very dilute but otherwise normal urine and by an enormous thirst

Incidence—It is a relatively rare condition which chiefly affects young people and is seen in males more frequently than in females The importance of heredity has been well illustrated by the study of a number of interesting families one of which (reported by Weil) included twenty three victims of persistent polyuria among the ninety one members of four generations

Symptoms—There are two general groups of cases (1) the so called *primary* or *idiopathic* in which no organic disease is demonstrable and (2) the *secondary* or *symptomatic* which is associated with an organic lesion of the brain or other parts. The lesions mainly associated with this second type are those produced by fracture of the base of the skull and other cranial injuries, basilar meningitis especially of syphilitic origin tumors of the brain particularly those of the hypophysis and neighboring structures cerebral hemorrhage encephalitis etc There are also reports of its association with tumors and aneurysms within the abdomen and with tuberculous peritonitis In cases of the *primary type* there may be no symptoms except those of the *diabetes insipidus* and at autopsy no characteristic gross lesions except perhaps some enlargement and congestion of the kidneys dilatation of the ureters, and hypertrophy of the bladder In the secondary type the symptoms may be numerous and are those characteristic of the associated lesion

The disease which may be congenital may begin suddenly after an injury, after an emotional shock or after an infectious disease Usually the onset is insidious with gradually increasing polydipsia and polyuria Trousseau's famous patient secreted 43 liters of urine in twenty four hours and drank a corresponding quantity of fluid It is said that one child passed a quantity of urine in one day the weight of which almost equalled that of the boy himself Usual quantities vary from 8 to 12 liters in twenty four hours The *urine* is quite pale, almost colorless of low specific gravity (1 001-1 005) and contains as a rule no abnormal elements The *thirst* is sometimes insatiable or the satisfaction of it may be the greatest pleasure of life When deprived of water the patients may suffer extremely and under such circumstances they have been known to drink their own urine It is easy to imagine the deleterious effects especially on a nervous person of the inconvenience the embarrassment the interference with daily activities but particularly of the insomnia so often produced by the frequent necessity of arising at night to allay the thirst and to pass urine Nevertheless in some cases the general health is satisfactorily maintained

and patients may live with the disease for fifty years The course of the secondary form of the disease depends upon that of the associated lesion and as might be expected the general health often fails rapidly

With the marked polyuria there are evidences of a lack of fluid elsewhere in the body the quantity of saliva is decreased, the skin is dry there is no sweating and constipation develops While the concentration of the urine is very low a normal amount of solids is passed in twenty four hours Increase of the nitrogenous food intake leads to increased output of nitrogen in the urine and an increase of the chlorides in the diet also increases the quantity excreted but with a great aggravation of the polyuria When the fluid intake is restricted the specific gravity of the urine rises somewhat and the amount of urine diminishes but not to normal In most cases after the hypodermic injection of pituitrin the polydipsia and polyuria practically disappear the concentration of the urine becomes normal and all renal functional tests are normal No significant metabolic disturbances have been demonstrated other than that of the water balance and the delicate adjustment in the blood between solids and fluids and in the amount of dissolved substances is maintained as steadily as in health

Pathogenesis —The current status of this complex and intriguing problem may be briefly summarized as follows

Experimental and pathologic studies indicate that diabetes insipidus may be caused by a disturbance of the posterior lobe of the pituitary gland by a lesion involving certain nerve centers in the hypothalamic region or by the interruption of the nerve tracts that pass between the nerve centers and the posterior lobe of the pituitary Lesions of the pituitary stalk are particularly prone to be followed by this syndrome The removal of the entire pituitary gland may cause a temporary polyuria and polydipsia and Richter insists upon the importance of a persistent and functioning anterior lobe

The relative importance of hormonal influences is suggested by several observations namely (1) the experimental condition may be induced in animals whose kidneys have been denervated (2) the antidiuretic principle of posterior pituitary products is effective in the complete absence of autonomic nervous influences, (3) the experimental disease may be transmitted by the blood to another animal by cross circulation experiments and (4) the remarkable observation of Mahoney and Sheehan that the extreme polyuria and polydipsia produced in dogs by the occlusion of the pituitary stalk with a silver clip can be abolished by subsequent total thyroidectomy and reestablished by oral administration of de iccated whole thyroid gland Alternate states of extreme polyuria and oliguria could be produced at will

Diagnosis —*Diabetes insipidus* is usually easily distinguished from *diabetes mellitus* by the glycosuria and the high specific gravity of the urine during the latter disease Rarely the two conditions are coexistent

Hysteric polyuria may simulate *diabetes insipidus* This primary polydipsia is in most instances transitory and there are usually other evidences of hysteria

A large amount of urine of low specific gravity may be passed by some patients with chronic nephritis but the presence of albumin and casts in the urine the arterial hypertension and the results of renal function tests should make the diagnosis easy

Treatment —Treatment should be based upon a thorough study of each case Syphilitic cases should of course receive antisyphilitic therapy Cures have been reported following simple lumbar puncture following x ray therapy to the pituitary region and after the administration of the anterior pituitary like hormone that is contained in the urine of pregnant women

Usually cures are not obtained but symptomatic measures may be most helpful No attempt should be made to reduce the amount of liquid The diet should contain only the minimal requirement of salt but otherwise need not be restricted Of the many drugs that have been tried amidopyrine is occasionally helpful and may be given in 1 Gm doses at noon and at bed time

Products of the posterior lobe of the pituitary gland are of great value After a sufficient dose the thirst disappears and the concentration and the quantity of urine become comparatively normal As a general rule it is most effective when administered

subcutaneously two to four times a day A trial may be made of the intranasal application of pituitary products A liquid may be used as a spray or on pledgets of cotton placed high in the nasopharynx Recently it is said that a more effective method has been found in the use of snuff of posterior lobe powder When this last named method is effective the administration becomes quite simple and the cost is greatly reduced

LIPOMATOSIS

Definition—Various observers have described a number of different types of localized or unusual deposition of fat all of which may be grouped under the term lipomatosis' to distinguish them from the ordinary form of obesity Lyon has pointed out the transitions between types and considers them not clinical entities but variations of a common morbid process

Clinical Types—(1) *Nodular Circumscribed Lipomatosis*—Single or multiple encapsulated lipomata are very common vary greatly in size and affect women more frequently than men They are soft and lobulated as a rule and although they usually cause no symptoms may be tender or even spontaneously painful When very numerous or very unfortunately situated they may cause mechanical interference with normal functions

(2) *Diffuse Symmetric Lipomatosis* (FETTHALS, ADENOLIPOMATOSIS—In diffuse symmetric lipomatosis the fatty masses are not encapsulated, they are more common in men than in women may be of very large size, and very disfiguring The term 'fat neck appropriately indicates the marked predilection for this region Huge masses may cover the shoulders and extend down the arms or may be arranged in segmental fashion on the thorax Sometimes there is a remarkable localization in regions rich in lymph glands so that at first sight a disease of these structures is suggested Lymphoid tissue or hemolymph nodes may be found in the masses but are no more characteristic of this type than of the other forms of lipomatosis Although symptoms are usually absent those more characteristic of Dercum s syndrome may be present

(3) *Adiposis Dolorosa* (DERCUM S DISEASE)—The cardinal features of *adiposis dolorosa* are fat deposits pain asthenia and psychic manifestations The condition is much more common in women than in men and is apt to occur in fat neuropathic individuals at the time of the menopause Spontaneously painful very tender irregular deposits may appear in the subcutaneous fatty tissues On palpation they may resemble a caking breast or feel as though filled with a bundle of worms' Asthenia is usually a striking feature Rheumatic pains appear in muscles and joints The onset is insidious Exacerbations and remissions occur, but the symptoms usually persist to some extent

(4) *Adipositas Cerebralis*—Under the heading of *adipositas cerebralis* may be grouped all disturbances due to intracranial lesions or associated with a deficient functioning of the hypophysis The *dystrophia adiposo genitalis* of Frohlich (1901) is the classic example The symptoms of such cases with a gross lesion usually a tumor of the hypophysis or neighboring structures may be

(a) Due to the brain tumor
   (1) General symptoms of increased intracranial pressure headache vomiting etc
   (2) Neighborhood symptoms due to local pressure visual disturbances hemianopsia optic atrophy changes in the sella turcica

(b) Referable to the loss of hypophyseal function (?), adiposity genital dystrophy, perhaps polyuria, and so on

(5) *The Lipomatosis of the Pseudohypertrophic Form of Muscular Dystrophy*—In lipomatosis of the pseudohypertrophic form of muscular dystrophy the dystrophic muscle groups may be strikingly enlarged by marked infiltration of adipose tissue between the muscle bundles There may also be unusual fatty deposits in the mammary and inguinal regions

(6) *Lipodystrophia progressiva* a rare condition in its fully developed form begins in childhood and affects girls almost exclusively It is characterized by a sadly disfiguring emaciation of the upper portion of the body with a remarkably complete disappearance of subcutaneous fat and by a grotesque obesity of the lower half of the body The general health may be good but there are often psychoneurotic symptoms

Morbid Anatomy—At autopsy in cases of lipomatosis the associated lesions of other structures especially of the endocrine glands are of considerable interest but the variety of the lesions even in cases belonging to the same clinical group prevents any clear understanding of the relationship Even in *dystrophia adiposogenitalis* different structures have been affected and some disturbances have been attributed to primary gonadal changes In Dercum s disease pituitary tumors have been found as well as thyroid changes Marine believes that atrophy of the thyroid is the characteristic lesion Degenerative changes in the peripheral nerves have been noted and may account for some of the symptoms

It is universally recognized that these fatty peculiarities are of endogenous origin but there is question as to whether they are due to disturbances in hormones (internal secretions), to changes in the nervous stimuli or depend upon powers inherent in the cells of the subcutaneous tissue Each theory has its advocates and it may be that all three are in some way combined

Treatment, except when the fatty masses may be removed by operation is unsatisfactory Small doses of dried *thyroid* or of *thymoxin* may be of value in *adiposis dolorosa* and whenever the metabolic rate is retarded *Pituitary extracts* may be tried in appropriate cases *Leptynol* is a German preparation of palladium in lanolin for local injection into fatty masses The *dietetic hygienic regimen* should be adapted to the state of general nutrition

HEMOCHROMATOSIS

Definition—*Hemochromatosis* or *bronze diabetes* is a disease of metabolism characterized by a marked *deposition of pigments* especially the iron containing hemosiderin in many organs of the body by *cirrhosis* particularly of the liver and pancreas and in most cases by *diabetes*

Incidence—Sheldon has collected 311 cases of which thirteen were in women The disease usually appears in middle aged men but though symptoms begin at this time of life it is evident that the pathologic process originates many years earlier

Etiology—The cause of hemochromatosis is not understood There is difference of opinion concerning the relationship of the pigmentation and of the cirrhosis to each other There is a marked disturbance of the intracellular iron metabolism although that of the hemoglobin seems to escape entirely There is a marked retention of iron in the body as much as 40 Gm or ten times the normal amount and as it seems from metabolism experiments that the retention is not complete many years must be required for its accumulation The chemical analyses of organs indicate some retention also of copper sulfur and calcium The possibility of copper poisoning in the etiology of hemochromatosis has been stressed by Mallory and others but recent work does not tend to support it The diabetes is generally attributed to the pancreatic lesion but the wide involvement of the endocrine glands is of possible importance in this connection

Morbid Anatomy—At autopsy the en

larged, cirrhotic liver, the pancreas, and the lymph nodes draining these organs are of a striking ochre color Other glandular organs show relatively slight macroscopic pigmentation Histologically hemosiderin is found in large amounts in the liver, pancreas and lymph nodes, and in smaller amounts in the other important glandular structures as well as in the spleen the heart muscle and, in some cases in the capillary endothelial cells of the skin and of the genito urinary tract Hemofuscin a finely divided, light yellow pigment, which does not contain iron, may be found in connective tissue and smooth muscle cells Physiologic pigments are increased

Symptoms—The early symptoms may be those of diabetes In other cases the *onset* is insidious, with asthenia and malaise, or sometimes a complication, such as tuberculous peritonitis, may be the first manifestation

The *skin pigmentation* in well marked instances has a distinct bronze shade and in extreme cases may be even bluish black The mucous membranes are usually not pigmented The *liver* is enlarged and may be tender The *spleen* is usually palpable and firm There is no *jaundice* and no characteristic change in the blood beyond the *slight secondary anemia* so frequent in chronic disease The endocrine involvement may be manifested clinically Genital hypoplasia is fairly frequent The diabetes is usually severe

Diagnosis—A diagnosis of hemochromatosis is suggested by the association of asthenia malaise skin pigmentation enlargement of the liver, and palpability of the spleen, with or without diabetes It may be confirmed by the finding of hemosiderin in the urinary sediment or in a section of excised skin but negative results of these tests are not conclusive

Prognosis—The prognosis is unfavorable After symptoms appear the disease lasts only a few months or at best a few years About 50 per cent of the reported cases have died in diabetic coma The duration of the symptomatic stage has been lengthened since the advent of insulin

Treatment must be symptomatic since our knowledge does not permit rational etiologic therapy The diabetes should be treated like the ordinary type of *diabetes mellitus* About 70 per cent of the cases respond favorably to insulin Some cases are hypersensitive, a few are resistant, to insulin

OCHRONOSIS

Definition—Ochronosis is a rare metabolic pigmentary disorder which results in darkening of the cartilages and certain of the fibrous tissues and in pigmentation of the skin Degenerative cartilaginous changes may develop into arthropathies

Incidence—There have been reported between forty and fifty cases which may be divided into three groups (1) those associated with alcaptonuria a constitutional familial anomaly of the metabolism of the aromatic amino acids which is manifested by the excretion in the urine of homogentisic acid normally an intermediary product of amino acid catabolism Such urine turns brown on standing or after the addition of alkali (2) Those associated with the prolonged use of carbolic acid applications (3) A smaller group in some of which melanin instead of homogentisic acid may be found in the urine Ochronosis is more frequent in men than in women and usually affects older people

Morbid Anatomy—The most heavily pigmented structures the cartilages of the ears trachea bronchi ribs intervertebral disks and symphysis are dark gray or black Those most involved become degenerated and worn and there is new bone formation (osteo arthritis) The pigment is apparently a melanin and appears microscopically as finely divided yellowish brown granules or else colors the tissue diffusely

Etiology—The etiology of the disturbance is not thoroughly understood but in all cases there is doubtless a large constitutional (probably inherited) factor Most alcaptonurics do not show ochronosis and consequently the causes of the two conditions cannot be exactly the same It is generally believed that melanin is formed from proteins through the aromatic amino acids probably through the activity of tyrosinase

Symptoms.—There may be no symptoms The earliest manifestations consist of a bluish coloration of the ear cartilages black flecks or streaks in the sclerae the slight pigmentation of the skin of the face In advanced cases there is marked skin pigmentation discoloration of the tendons of hands and feet greenish brown axillary sebum a brownish black cerumen and usually an osteo arthritis especially of the larger joints The urine of course should be carefully examined

Treatment—Careful search should be made for any possible extrinsic cause such as the use of carbolic acid or exposure to similar chemicals Attempts may be made to reduce the exogenous protein component by reducing the dietary protein to the minimum 0 7 to 0.8 Gm per kilogram of body weight and selecting proteins of low tyrosine and phenylalanine content The joint symptoms may be treated as in other types of osteo arthritis

OBESITY

Definition—Obesity is a state in which the amount of fat stored in the body is excessive

Incidence—Obesity is one of the commonest ailments to which the flesh is heir and is of importance to the individual in proportion to its degree and its association with other diseases To the community it is of importance in that it may *per se* decrease human efficiency and shorten human life The latter is proved conclusively by the data of life insurance companies

Etiology—The fundamental cause of obesity is a positive energy balance That is the caloric value of food absorbed is greater than the total expenditure of energy A comparatively slight disproportion between fuel intake and combustion may over a period of years result in a marked grade of obesity Indeed the extraordinary thing is not that so many persons become obese but rather that more do not Most persons preserve a constant and normal weight in spite of marked variations in their bodily activity and without conscious regulation of their food intake This is because the normal appetite ordinarily adjusts intake so accurately that it just meets but does not exceed the requirements of energy expenditure When this adjustment loses its delicacy and eating falls under the rule of habit obesity may develop Rationing will probably reduce the incidence of obesity

Morbid Physiology—Obesity may be divided into two main types sometimes called exogenous and endogenous In the exogenous variety the acquisition of excess weight coincides with either an increased ingestion of food or a decrease in bodily activity or both the fundamental rate of oxidation in the body remaining unchanged In the endogenous type the explanation of the weight gain is traceable to a drop in fundamental rate of oxidation in the body due to a disturbance in the function of one or more of the endocrine glands It is important to note that in either type the excess storage of fat is due to a simple disproportion between the intake of food and the energy requirement of the body The endogenous cases are endogenous merely in the sense that in the creation of such a disproportion a fall in the rate of oxidation in the body

plays a role Coming in this category may be mentioned obesity associated with hypothyroidism, with hypopituitarism (Frohlich s syndrome of *dystrophia adiposogenitalis* also Dercum s disease and Cushing s syndrome) and with dystrophies of the gonads A much greater proportion of obese persons belongs to the exogenous group

That no fundamental alteration in rate of combustion exists in simple or exogenous obesity is amply proved by studies of the so called 'basal metabolic rate For example by the DuBois standards a series of 41 obese persons studied at the Massachusetts General Hospital showed an average variation from the expected metabolism of but 0.5 per cent Similar results have been obtained by others

Nevertheless it is a matter of common belief that certain persons tend to gain weight while others *apparently* eating as much and exercising no more do not The explanation of this is not to be found in the kind of food ingested The ratio between total calory intake and total calory output is what counts All excess calories after the glycogen depots are filled are stored in the body in the form of fat whether they were originally derived from fat protein carbohydrate or alcohol Differences in energy reaction to similar stimuli may explain some of the differences in the tendency to gain weight While the basal metabolic rate of an individual who gains weight readily may be the same as that of one who does not their total metabolisms may be different and it is the total metabolism in relation to fuel intake which determines weight behavior The performance of muscular work and the ingestion of food accelerate metabolism so do emotional disturbances probably through the liberation of adrenalin Total metabolism consists in basal metabolism plus the increments due to all these causes It is entirely possible that the individual who gains weight readily reacts less intensively to such stimuli than one who has no such tendency In the former the total metabolism would be less than in the latter even though the basal rate of the two were the same

For the most part clinical experience bears out such an hypothesis Individuals who gain weight readily even though they apparently do not eat to excess are usually phlegmatic, they worry less, sleep either longer or more soundly and when at rest relax more completely than persons of the normal or thin types

Morbid Anatomy—In the milder grades of obesity there is simply an excess of fat in the normal fat depots such as the subcutaneous and retroperitoneal tissues, the breasts and the omentum In the severer grades fat infiltration is found also in parenchymatous organs such as the heart and liver

Symptoms—Slight degrees of obesity cause no symptoms As adiposity increases, the extra weight of itself gives rise to a certain amount of dyspnea on exertion and perhaps to increased tendency to fatigue When the obesity becomes extreme the state of corpulence alone may lead to mechanical limitations finally ending in nearly complete incapacity The symptomatology of obesity is however most conspicuously of an indirect variety The added burden of fat puts the whole body under the strain of extra work which manifests itself in an exaggeration of the symptoms due to any coexisting morbid tendency As a recent writer has well put it fat is a parasite The patient suffers chiefly from the effect of his obesity upon his other bodily weaknesses Thus the cardiac patient who becomes obese is in increased danger of cardiac failure and the kidneys pancreas and liver of the obese carry an abnormal load It is generally conceded that obesity predisposes to diabetes and it is also true that often the obese have moderate arterial hypertension which tends to decrease when their weight is reduced

Diagnosis—Inspection gives the diagnosis The determination of cause is the important thing The habits of eating and exercise should be investigated and an attempt made to discover whether the cause lies in excessive food intake insufficient exercise or both Upon such an evaluation will depend the success of treatment The existence of endocrine factors must also be determined Metabolism studies aid in the recognition of these In the thyrogenous obesity the basal metabolic rate is invariably decreased

Prognosis—The prognosis depends upon the grade of obesity and the willingness of the patient to reduce Acute infections par-

ticularly pneumonia also cardiac and renal lesions are more serious in the obese particularly in the very obese than in otherwise normal persons

Treatment —Prophylaxis is better than treatment It is easier to prevent obesity than to cure it The family physician should encourage patients to weigh themselves and keep their waist measure from increasing The treatment of any type of obesity lies in the correction of the disproportion between the intake and expenditure of energy To that end we may restrict food consumption and increase bodily activity The treatment is therefore essentially *dietetic* and *hygienic* Drugs are indicated for the complications only For success in treatment the patient s cooperation is essential No one can be satisfactorily reduced who does not wish to be It should be remembered that most fat persons though they may not admit it take delight in eating Food intake with them has fallen under the head of habit instead of instinct With the physician s help the habit can be gradually broken and the patient satisfied with an adequate instead of an excessive amount of food In women a desire to reduce often springs from vanity and in either sex this desire may be stimulated by a thorough explanation of the dangers of corpulence

The *indications* for a reduction cure depend on *several factors such as the patient s* age (reduction cures are less worth while in the elderly) the degree of obesity and the existence of complications In the slightly overweight otherwise healthy subject the indication may be for the regulation of diet and exercise only to the point of preventing further gain Sometimes the forbidding of candy alone or of excess butter cream sugar or bread will accomplish this In the somewhat more obese but still otherwise healthy patient the regulation must be more strict and a loss of weight sought The physician *must follow his patient until* the desired reduction has been achieved and thereafter guard against a recurrence He must decide upon the desirable amount and rate of loss in weight In the former he will be guided by standard figures for the weight of normal persons The rate of reduction will depend on the degree of obesity In marked grades it may be as rapid as three to four pounds a week In mild or moderate grades it need not be so rapid At the beginning of a reduction cure there is apt to be a rapid loss of weight chiefly due to water loss *Also as the reduction goes on there may be alternating periods of loss and absence of* loss due to fluctuation in water excretion and storage

A variety of reduction diets has been proposed None possesses any unique virtue The dietetic indication is simply to decrease total fuel intake without destroying the proper balance of the ration or depriving the body of vitamins The amount of protein allowed may be liberal and seldom should be reduced below 60 to 70 Gm A restriction below that might lead to the destruction of body protein thus weakening the patient The restriction should be chiefly in fats and the concentrated carbohydrate foods sugar and breadstuffs Fruits and the low carbohydrate vegetables are invaluable since through their bulk they not only reduce the pangs of hunger but also supply certain vitamins The physician with the use of food tables must plan the diet to meet the requirements of the individual patient In extreme grades of obesity Newburgh advocates diets as low as 300 calories per diem and commonly uses ones of 450 calories made up of 60 Gm of protein 10 Gm of fat and 30 Gm of carbohydrate It may be *desirable to increa e such diets to 600 or* 800 calories after a month or two in order to prevent ketosis which will occur in very obese young persons when they become really active These low diets should be reinforced with vitamins Less drastic reduction diets of 1200 or 1400 calories can be continued for long periods if accessory food substances are supplied in adequate amounts A program of gradually increased exercise should be combined with diet restriction Prolonged and gentle exercises are better than short violent ones

Thyroid will reduce weight by accelerating metabolism but there is the undesirable feature that symptoms of hyperthyroidism may also be produced Ordinarily, therefore thyroid should be used for reduction only when the basal metabolic rate is low Dinitrophenol has been widely heralded as the ideal reducing agent It raises metabolic rate and so causes reduction usually without un

pleasant symptoms It can, however, produce serious even fatal toxic injury, and consequently its use cannot be recommended

Amphetamine sulfate (Benzedrine sulfate) has recently become a popular drug for weight reduction Amphetamine appears to reduce weight by decreasing the patient's desire for food The dose is 5 to 10 mg twice a day Because of its stimulating effect and its tendency to produce insomnia the drug should not be taken late in the day

It has been found lately that rapid weight *losses sometimes produce or precipitate* thyrotoxicosis

UNDERNUTRITION

(*Thinness Inanition*)

Definition —Undernutrition is the physical state resulting from the failure to ingest assimilate or utilize any or all of the substances essential for normal body metabolism Undernutrition may or may not be associated with thinness (subnormal body weight) and is therefore not to be considered simply the opposite of obesity When thinness alone is present the nutritional defect is due to inadequate caloric intake or to interference with the absorption and storage of energy supplying and fat forming foods Usually undernutrition is not confined to a single deficiency and lack of several or many food elements is detectable

Incidence —Recently numerous studies have led to the impression that a suboptimal nutritive state is much more common than previously recognized No general statistics are available since there have been no complete surveys of the population and the criteria for diagnosis have varied widely

Etiology —Nutritional deficiency may be due to inadequate intake defective absorption excessive destruction or elimination of one or more necessary food substances The materials required for optimal health and efficiency include carbohydrate fat protein the vitamins and certain minerals

Inadequate Intake —Many diets in America are deficient in thiamine (vitamin B_1) *nicotinic acid (niacin)*, ascorbic acid and calcium, resulting in recognizable clinical deficiency states, even in the presence of adequate caloric intake and normal body weight This is the result of economic factors in some instances but more often is caused by poor food selection due to habit or ignorance with consequent excessive intake of refined cereals white bread and sugar and neglect of whole wheat products fruits vegetables and milk Failure of intake of the necessary foods may result from organic disease causing inflammation or obstruction of the alimentary tract, vomiting nausea or anorexia Loss of appetite is a frequent symptom in many organic and functional disorders and is common in certain psychotic and psychoneurotic states Thus the clinical picture in a number of diseases may when food ingestion is insufficient be complicated by the development of a general or specific nutritional defect When intake is inadequate in only one of the essential constituents of food a characteristic disease picture may occur such as scurvy due to lack of ascorbic acid or hypochromic anemia due to lack of iron In instances of more or less general undernutrition the clinical syndromes characteristic of several vitamin mineral or other food deficiencies may appear together

Inadequate Absorption —Chronic diarrhea is the commonest factor interfering with absorption and assimilation of nutritive elements Other factors in this category are the absence of important enzymes (*e g* lack of pancreatic lipase resulting in steatorrhea) Other examples are the poor absorption of iron in the absence of adequate gastric hydrochloric acid and poor calcium absorption with deficient vitamin D

Increased Metabolism—When intake and absorption are enough for average normal requirements but cannot satisfy metabolic demands in special circumstances a relative deficiency exists which may often be corrected by increasing the amounts ingested To the basal caloric requirement for adults one must add not only calories in proportion to activity but an additional supply of vitamins and minerals Children require large amounts of energy foods plus liberal protein iron vitamin D and calcium if activity and growth are to be provided for and anemia and rickets prevented Pregnant and lactating women require more calcium and phosphorus than nonpregnant women because of the demands of the fetus or nursing Weight loss and vitamin deficiencies may occur in prolonged fever or thyrotoxicosis because of the accelerated metabolism Chronic inactive low grade infections such as tuberculosis chronic tonsillitis and chronic arthritis may keep a patient underweight even in cases where there is no fever In such instances undernutrition is presumably due to the effect of toxins on the metabolism Patients with diabetes become depleted of carbohydrate stores lack energy and become thin as the result of prolonged glycosuria Uncontrolled diabetics must utilize large amounts of body fat for energy and thus lose weight

Pathologic Physiology.—Since the possible types and causes of undernutrition are numerous and complex in nature there are no patterns of physiologic or chemical disturbance common to all cases Certain general considerations are nevertheless pertinent Foodstuffs may be classified according to their functions (1) as structural or supportive material (bone cartilage skin connective tissue stroma of individual organs and cells) (2) as fuel (for body heat for muscular activity and work as well as for the energy for numerous complex intermediate metabolic processes) and (3) as catalytic substances or chemical regulators

Most foods fall into more than one of these three categories By far the greatest proportion of carbohydrate is used for fuel but some is used in the production of special conjugated proteins in cartilage Some carbohydrate apparently is needed for certain enzymes Fats are primarily used for fuel but furnish some structural support Proteins are most important as structural material but are also important in the formation of enzymes and hormones and thus may also furnish catalytic substances and chemical regulators Protein can also be used as fuel when other fuel supplies are deficient or when protein is present in excess Calcium is used primarily to build bone It also acts as a catalyst in blood clotting and as a chemical regulator of neuromuscular activity Vitamins are essential food substances not utilized in structure or as fuel but as catalysts in certain important metabolic reactions Nicotinic acid for example becomes a component in two important coenzymes coenzyme I and coenzyme II both concerned in glycolysis and tissue respiration

With these functions of foods in mind it is evident that a deficiency in any single nutrient is apt to be reflected by more than one physiologic or chemical disturbance Nevertheless when the lack is chiefly of one food element certain typical changes may predominate These are presented in Table 1

Optimal nutrition includes not only provision of the materials essential for structure fuel and chemical regulation but for storage of certain reserves against unusual demands During an emergency such as fever vomiting or diarrhea fuel requirements will be met but if the fuel requirement exceeds the caloric intake for any prolonged period some of the energy must be supplied from body stores of glycogen and fat The patient may then become thin no matter what the cause of the negative energy balance When food intake is persistently insufficient to compensate for metabolic demands a chronic poorly nourished state is to be expected

In certain instances patients may remain thin when the caloric content of the diet seems more than enough to induce weight gain In the absence of an increased basal metabolism or of a digestive or absorptive disorder it must be concluded in such cases that the total metabolism exceeds the intake All careful metabolic studies support this conception which is only the application to human metabolism of the first law of thermodynamics Thin persons who are otherwise healthy often can be shown to expend more energy at work and in restless

movements and to relax less completely and sleep less soundly than normal persons having the same basal metabolism and body measurements When appetite and food intake remain excessive but weight loss progresses two possible explanations must always be considered hyperthyroidism or diabetes mellitus Failure to gain weight or steady weight loss may occur from any prolonged fever, for example in tuberculosis or brucellosis

ure Specific signs of lack of certain food elements may be present, e g osteoporosis with fractures of bone or collapse of vertebrae as the result of calcium lack soft bleeding gums and hemorrhages into the skin due to deficiency of ascorbic acid, dermatitis and glossitis of pellagra

In many instances the pathologic picture resembles closely that of pituitary cachexia (Simmonds disease) It seems likely that the pituitary failure may be primary in cer-

TABLE 1 —RESULTS OF INADEQUATE DIET

FACTOR LACKING	FOODS LACKING	RESULTS
Calories	Carbohydrates fats	Thinness lack of energy failure to grow
Protein	Eggs meat milk wheat corn rice peas beans	Muscle wasting hypoproteinemia edema
Calcium	Milk	Defective bones and teeth rickets osteomalacia and tetany in pregnancy
Vitamin A	Green vegetables carrots tomatoes milk eggs butter fish liver oils sweet potatoes	Xerosis of conjunctiva and cornea night blindness follicular hyperkeratosis
Vitamin B_1 (thiamine)	Whole cereals milk meat (especially liver and pork)	Beriberi polyneuritis
Vitamin B_2 (riboflavin)	Milk eggs liver green vegetables	Cheilosis glossitis ocular disorders
Nicotinic acid (niacin)	Milk lean meat liver	Pellagra stomatitis glossitis dermatitis
Vitamin C (ascorbic acid)	Oranges lemons grapefruit tomatoes	Scurvy capillary fragility hemorrhages, anemia
Vitamin D (calciferol)	Fish fish liver oils milk eggs liver (sunlight)	Rickets osteoporosis osteomalacia
Vitamin K	Green leaves spinach cabbage kale cauliflower egg yolk liver	Prothrombin deficiency hemorrhages resulting from prolonged bleeding and clotting time
Iodine	Fish iodized salt	Goiter
Iron	Meat liver eggs beans prunes peas wheat oatmeal spinach	Hypochromic anemia especially during growth menstruation pregnancy blood loss
Extrinsic factor	Muscle meats eggs wheat germ liver	Hyperchromic macrocytic anemia

Morbid Anatomy —Extreme undernutrition may result in death within a short time Less severe degrees of nutritional failure may result in emaciation and weakness which may persist for years with loss of practically all body fat muscle atrophy and evidence of premature aging The skin becomes dry, inelastic and wrinkled the hair becomes dry and gray and falls out teeth become carious and are lost and there may be evidence of pituitary, thyroid and gonadal failure tain cases leading to anorexia prolonged inadequate food intake and failure of the other glands of internal secretion When prolonged undernutrition results from anorexia nervosa or from any condition preventing adequate food intake for a long time pituitary failure may occur as one consequence of the severely disturbed body metabolism Atrophy of the other glands of internal secretion may follow with such changes as amenorrhea atrophy of sex or

gans and low basal metabolism Experimentally pituitary changes have been produced by chronic inanition and pituitary changes may be found following deaths attributed to anorexia nervosa

Persons who are undernourished have decreased resistance to infection and their tissues heal poorly after trauma Therefore infections of the skin bladder kidneys and lungs are common and ulcers of the mouth gastro intestinal tract or skin occur frequently

Moderate undernutrition may be manifested only by scanty body fat if the deficiency is primarily caloric or by one or more specific anatomic defects when there is a lack of certain particular foodstuffs such as vitamins or minerals (see Table 1)

Symptoms —Mild or early states of nutritive failure do not produce the striking signs or symptoms of emaciation or of beri beri pellagra or scurvy Vague ill health may be the first warning Lack of energy easy fatigue irritability mental depression headache and insomnia may appear and the patient may be said to be neurasthenic or to be constitutionally inferior There may or may not be weight loss Loss of appetite and gastro intestinal disturbances such as vomiting and diarrhea may further reduce the intake of essential food elements The body stores become depleted Disturbances in biochemical reactions necessary to normal body metabolism soon result Functional evidence of certain metabolic derangements may become more evident *e g* nightblindness paresthesias or pains in the extremities suggesting specific nutritive deficiencies Later may appear anatomic lesions identifying the condition as due to a single or more often to a multiple nutritive defect When the typical gum changes and hemorrhages of scurvy or the muscle wasting hypoproteinemia and edema of protein deficiency or the classic bony softening and deformity of osteomalacia occur it is not difficult to identify the disorder Before definite physical evidences such as changes in the mucous membranes skin eyes bones muscles or reflexes occur however diagnosis may be difficult This is necessarily so because of the numerous combinations of symptom complexes which occur with various multiple nutritional deficiencies Single deficiency states are rare so when there are symptoms of one the evidence of others should be sought

Diagnosis —The detection of undernutrition to be most effective should be early before florid signs of nutritional failure appear Four successive stages may be distinguished (1) tissue depletion (2) biochemical disturbances (3) functional changes and (4) anatomic lesions History of dietary inadequacy failure to absorb failure to utilize or hastened destruction or excretion of one or more dietary essentials is valuable Poverty bad food habits chronic alcoholism or a psychic disorder may be suggestive of poor intake Gastro intestinal symptoms may imply absorptive failure A febrile or metabolic disease may cause enough increased utilization destruction or elimination of nutritive elements to cause nutritional failure

Tissue depletion may be advanced before symptoms develop Weight loss when accompanied by fatigue irritability headache insomnia and depression is especially suggestive Our present technics are inadequate for detection of nutritional deficiencies in the stages before definite signs and symptoms develop but progress in this respect is rapid Only deficiency of protein (hypoproteinemia) vitamin K (lengthened prothrombin time) and vitamin C (low whole blood ascorbic acid) are now detectable by blood examination prior to the development of anatomic lesions High blood pyruvic acid when accompanied by suggestive symptoms implies thiamine deficiency Biomicroscopic eye examination may reveal capillary invasion of the cornea (riboflavin deficiency) or changes in the conjunctiva (vitamin A deficiency) Chemical determination of serum calcium phosphorus and phosphatase may suggest vitamin D lack or insufficient intake of these minerals Study of the number and morphology of the red blood cells and blood hemoglobin measurements may disclose anemia from iron deficiency or lack of ' extrinsic factor X ray examination of bones and joints will reveal lack of development in undernourished children or distorted development as in rickets Evidences of osteomalacia osteoporosis or scurvy may be thus detected in adults The chief clinical syndromes and anatomic lesions occurring in various deficiency states are given in Table 1

Tentative goal toward which to aim in planning practical dietaries can be met by a good diet of natural foods Such a diet will also provide other minerals and vitamins the requirements for which are less well known Reprinted from the J A M A June 7 1941 page 2601

* Requirements may be less if provided as vitamin A greater if provided chiefly as the provitamin carotene
† One mg of thiamine equals 333 international units 1 mg of ascorbic acid equals 20 international units
‡ Vitamin D is undoubtedly necessary for older children and adults When not available from sunshine it should be provided probably up to the minimum amounts recommended for infants
§ Need of infants increase from month to month The amounts given are for approximately 6 to 8 months The amount of protein and calcium needed are less if derived from breast milk
¶ Allowances are based on needs for the middle year in each group (as 2 5 8 and so on) and for moderate activity

Prevention and Treatment —Prevention is greatly preferable to treatment Discovery of the cause of a nutritive defect and its elimination before there is evidence of disturbed nutrition is the most effective treatment When intake is insufficient correction of faulty food preparation or poor eating habits may be necessary From four to six small attractive meals are better than two or three large ones Insulin (5 to 15 units one half hour before meals) stimulates appetite in some cases Carminatives are occasionally effective Psychotherapy is frequently indicated Moderate regular exercise with proper recreation and rest are important

Wholesome natural foods should be selected as the source of calories since thus the required vitamins and minerals are more apt to be obtained Nutritionists have discovered widespread waste in the usual methods of food preparation Large amounts of valuable minerals and vitamins are often discarded in the outer coverings of fruits and vegetables and in the cooking water Faulty preservation or the heat of cooking may destroy vitamins Treatment must supply sufficient amounts of all essential nutrients (calories proteins fats carbohydrates minerals vitamins and water) When a patient is quite ill or has a greatly increased requirement he may be unable to ingest or utilize adequate quantities of the usual foods In such instances concentrates or crystalline substances should be employed in proper amounts as supplements to the diet Tube feeding or parenteral administration of the most important nutrients may be imperative in severe illness

Prevention of nutritional disorders is facilitated by remembering that the commonest dietary factors lacking are calcium iron vitamins A and D vitamin B complex ascorbic acid and proteins of high biologic value (containing the essential amino acids) The use of enriched bread (with added thiamine nicotinic acid and iron) should be urged upon persons taking inadequate amounts of whole cereal foods In estimating optimal nutrient intake (see Table 2) account must be taken of age, sex size muscular activity pregnancy lactation and growth An average normal adult should eat each day at least the following protective foods (plus carbohydrate and fat sufficient to supply the necessary calories) 1 pint of milk 1 egg 1 serving (3 to 4 ounces) of meat 3 teaspoons (15 Gm) of butter, 4 servings of whole grain bread or cereal 2 vegetables other than potato (one green) 2 fruits one of which is raw

ACIDOSIS

Definition — Acidosis is the term usually employed to designate a reduction of the bicarbonates (alkaline reserve) in the blood below the normal level

Blood is a complex buffer solution A buffer solution is one to which considerable amounts of acid or alkali may be added with a minimum change in reaction (hydrogen ion concentration) The chief constituents of the blood contributing to its buffer qualities are the proteins hemoglobin bicarbonates phosphates carbonic acid chlorides free oxygen and ammonium salts Of greatest importance are the bicarbonates because of their relatively great concentration and the easily available base for the neutralization of acid radicals

A less common use of the term acidosis and of less importance clinically is in connection with an *increase in the hydrogen ion concentration* of the blood above the normal range The reaction (hydrogen ion concentration) of the blood depends not so much on the concentration of the bicarbonates and

other buffer substances as on the relative amounts or ratio of weakly dissociated acids and their bases Blood reaction is customarily reported as the logarithm of the actual value of the hydrogen ion concentration using the notation *p*H The normal *p*H range is between 7 35 and 7 45 Since the acid base ratio is the important factor in maintaining a hydrogen ion concentration within very narrow limits in order that the life of the cells may not be endangered the expression acid base equilibrium is frequently used in connection with the reaction of the blood and body fluids

Under average normal conditions of activity and food intake the acid waste products of metabolism are in excess of the basic The mechanisms for coping with this contingency are (1) the buffer quality of the blood which maintains a constant reaction chiefly by combining the acid radicals with the base of the bicarbonate the liberated CO_2 passing off through the lungs (2) the excretion by the kidney of a urine much more acid than blood and the consequent return of base to the body to form bicarbonate ready for transporting more acid to the kidney and (3) the utilization of ammonia to combine with acid radicals to be eliminated as neutral salts

Occurrence —Whenever the removal of base occurs through the intake or production of acid which exceeds the capacity of the regulatory mechanism acidosis results In normal circumstances the regulatory mechanism encounters no difficulty from food intake and the products of metabolism The most common cause of acidosis is the excessive production of betahydroxybutyric and acetoacetic acids by faulty fat and protein metabolism Less frequently other organic acids may be produced in amounts sufficient to produce an acidosis

In the event of a derangement of the regulatory mechanism *conditions of acidosis may* arise as the result of the retention of acid radicals Disease of the kidneys may lead to a retention of phosphoric acid sulfuric acid and possibly other acids and a reduced capacity to utilize ammonia in the excretion of acid radicals A severe acidosis may be brought about through the removal of base by way of the bowel in the diarrheal diseases particularly in children

So far as is known at present acidosis is of clinical importance only if severe Varying grades of acidosis may appear in a variety of diseases *The more important conditions* in which acidosis may be present are

Diabetes Mellitus —Acidosis is one of the most serious features of *diabetes mellitus* in fact it is usually the cause of death Owing to the inability on the part of the diabetic to burn glucose there is a production of the ketone acids in excess of the ability of the organism to utilize them completely

Childhood —*Cyclic vomiting in children* is often associated with the production of large amounts of ketone bodies and a marked lowering of the alkaline reserve A disturbance in the metabolism of fat and proteins may occur suddenly in a perfectly healthy child The production of ketone bodies may be considerable and the acidosis extremely grave This condition is usually *accompanied by gastro intestinal symptoms* vomiting diarrhea and slight fever In the diarrheal diseases of children marked acidosis may be due to either the production of excessive amounts of an unidentified acid or the loss of base through the bowel

Renal Disease —In the terminal stages of chronic nephritis a very marked lowering of the bicarbonate of the blood is occasionally observed Less frequently acidosis is encountered in acute nephritis

Asiatic Cholera —A severe acidosis occurs in Asiatic cholera probably due to excessive loss of base through the bowel

Varying grades of acidosis *usually* mild may be observed in the infectious diseases during starvation in anesthesia pregnancy the chronic diseases with cachexia shock burns and poisoning with methyl alcohol salicylates and carbon monoxide *It* is seldom of any clinical significance

Diagnosis —Only marked acidosis can be recognized clinically The patients complain *of headache* weakness drowsiness and eventually become hyperpneic The characteristic fruity odor of the breath due to the excessive production of ketone acids may frequently be noted There are few conditions in which *laboratory tests are* of greater service than in the diagnosis of acidosis The information thus obtained is most useful when there is a distinct lowering of the alkaline reserve which is still insufficient to

produce clinical symptoms Early recognition of this frequently makes it possible to prevent serious acidosis

The most useful and reliable test is the *determination of the CO_2 combining power of the plasma* according to the method of van Slyke The normal range is 55 to 65 volumes per cent Values between 40 and 55 volumes per cent are indicative of mild acidosis The range between 30 and 40 volumes per cent is important While not in itself dangerous it represents the stage immediately before clinical symptoms appear and is the period when wise therapy may prevent a more serious condition Hyperpnea headache weakness and general malaise almost always are exhibited when the CO_2 combining power is in the neighborhood of 30 volumes per cent As the blood CO_2 diminishes the hyperpnea becomes greater and the drowsiness increases until deep coma supervenes at about 18 to 20 volumes per cent While patients may recover after the alkaline reserve has been reduced to 10 volumes per cent this level is extremely critical The author has seen recovery when the combining power had been reduced to 8 volumes per cent

So far as is known at present an increase in the hydrogen ion concentration of the blood without a lowering of the alkaline reserve is of secondary clinical importance

Prognosis—That acidosis is an abnormal physiologic state which may appear in a variety of pathologic conditions and *not a disease* should be clearly appreciated The prognosis then depends to a considerable degree on the underlying cause Prognosis should be guarded in any case with clinical manifestations for the more marked the clinical signs and the lower the blood CO_2 the greater the danger to the patient An important factor in prognosis is the response to treatment

Treatment—In nearly all conditions in which acidosis develops in severe form there is a depletion of water and base in the body The basis of rational treatment then is the restoration as rapidly as possible of the acid base equilibrium and water balance to within normal limits The diseased states in which the acidosis occurs have certain additional individual indications

Acidosis in diabetes mellitus is by far the most frequent and important form encountered in medical practice Treatment of diabetic acidosis consists in (1) amelioration of dehydration which may be associated with varying degrees of circulatory collapse and impairment of renal function (2) combating ketosis and (3) control of the diabetes

Relief from the physiologic effect of dehydration is *imperative* This is secured by the administration of adequate amounts of fluid and base Large amounts of fluid are often necessary and saline solution which supplies base as well as water is the solution of choice Not infrequently as much as 5 to 6 liters of saline solution in the first twenty four hours may be required In uncomplicated cases of diabetic acidosis in coma with a plasma CO_2 of 20 volumes per cent or lower the intravenous injection of 2500 cc of solution made up of 2000 cc of 1 per cent salt solution to which is added 25 Gm of sodium bicarbonate dissolved in 500 cc distilled water should be given without delay At least one hour should be allowed for the administration Thereafter 1000 cc of 5 per cent glucose in 1 per cent salt solution should be given intravenously every three hours until the patient s clinical condition is markedly improved *i e* until he is out of coma there has been a rise in plasma CO_2 and blood pressure and he is able to take fluids by mouth Where the acidosis is less severe and the patient is not in coma sodium bicarbonate may not be necessary and the amount of salt solution required to restore normal water and base balance may be less Most failures in the treatment of diabetic acidosis are due to the administration of insufficient amounts of fluid In the writer s clinic where the effect on the circulation has been followed by frequent venous pressure readings no harm has been observed in uncomplicated cases as the result of large infusions of saline glucose solutions

Fluids by mouth or rectum are ineffective When administered by hypodermoclysis they are much less effective than by vein Fluids by mouth for comfort when the clinical conditions warrant it are advisable Where the condition is complicated by hypertension, known cardiac damage pneumonia and in old individuals the administration of large amounts of fluids must be given with caution The best guide to the propriety of

continuing with intravenous saline solution in large amounts is the venous pressure When pneumonia is a complicating factor, venous pressure is an unreliable guide and large infusions should not be given An elevated venous pressure to start with is discouraging and one that increases as the result of infusion is a danger signal Should there be no diuresis within three hours following the first infusion and the blood pressure remains low, 90 mm or lower systolic, a transfusion of 500 to 700 cc of blood is indicated

Combating *ketosis* is essential This is best accomplished by giving immediately while preparing for the saline infusion 40 units of insulin subcutaneously if the blood sugar is 0 3 per cent or over and the urine sugar is 4 plus Ten units of insulin should be given every hour thereafter until the urine sugar becomes 2 plus

Such *general measures* as keeping the patient warm with hot blankets or hot water bottles, clearing out the lower bowel by enema and gastric lavage if the patient is vomiting should be instituted There is no medical emergency where hour to hour watching and meeting the indications as they arise is so essential to success as in severe diabetic acidosis Even after the patient comes out of deep coma and may appear to be improving rapidly sudden relapses occur and immediate treatment is necessary

The reader is referred to the article on diabetes for direction concerning dietary control Since the ketonic acids are largely derived from fats and to a certain extent from proteins both should be kept low The author prefers to restrict the fats to 20 Gm and proteins to 40 Gm with a fairly liberal allowance of 150 to 160 Gm of carbohydrate for the first two or three days following severe acidosis Insulin should be administered in amounts adequate to keep the urine sugar free

The acidosis which occurs in recurrent or cyclic vomiting of children if severe is best treated by intravenous administration of the appropriate amounts of saline solution and glucose If the plasma CO_2 is below 25 per cent and there is marked hyperpnea 5 to 10 Gm of sodium bicarbonate should be added to the first infusion The reader should consult textbooks of pediatrics for detailed discussion of this subject

In acidosis due to diarrhea saline infusions are usually adequate to control the situation If, however, the acidosis is severe sodium bicarbonate should be included in the first infusion and repeated if necessary

The acidosis associated with the terminal stages of chronic nephritis seldom requires treatment If hyperpnea develops to a point of making the patient uncomfortable sodium bicarbonate in small amounts either by mouth or intravenously may be employed Large amounts of sodium bicarbonate should be avoided owing to the danger of producing alkalosis to the point of causing tetany Several deaths are reported following the administration of large amounts of sodium bicarbonate to patients with chronic nephritis

Readers are referred to more comprehensive articles for a discussion of the theoretical consideration of the subjects where reference to the extensive literature may be found

ALKALOSIS

Definition—Alkalosis is the term employed to designate an increase in the bicarbonates of the blood above the normal level or an abnormal increase in the pH of the blood due to the loss of carbonic acid Reference may be made to the general discussion of the buffer systems of the blood in the article on acidosis

Occurrence—When alkalis are ingested or administered in amounts which cannot be eliminated by the kidney or bowel at a rate to prevent accumulation in the blood alkal

osis results On the other hand if the acid radical chlorine is eliminated from the body in excessive amounts the sodium thus released combines with carbon dioxide thereby increasing the bicarbonate in the blood Carbon dioxide may be lost from the blood through hyperventilation and in this manner reduces the acid in proportion to bicarbonate which results in an increase in the *p*H or an uncompensated gaseous alkalosis

Alkalosis of clinical importance is observed in patients who have received large amounts of alkali for therapeutic purposes as in the treatment of peptic ulcer or in combating acidosis Several instances of death following the administration of large amounts of alkali to chronic nephritics have been reported Before the introduction of insulin the writer observed several patients with diabetic acidosis who had received sodium bicarbonate in amounts sufficient to produce a high grade alkalosis in the presence of a ketosis Severe alkalosis may be produced by prolonged vomiting either due to obstruction or of neurotic origin and occasionally the condition is seen due to frequent gastric lavage Hyperventilation as a cause of alkalosis may be voluntary due to hysteria or as the result of a lesion in the brain

Diagnosis —Mild grades of alkalosis seldom produce symptoms As the condition increases in severity the patient may become restless irritable and excitable until finally *tetany* supervenes with the exhibition of Chvostek s and Trousseau s signs and the characteristic response of the neuromuscular system to galvanic current The signs and

symptoms of alkalosis are the same irrespective of the underlying cause The plasma CO_2 is the most reliable guide to the degree of alkalosis present except in cases of over ventilation

Treatment —Rational therapy is directed toward the correction of the disturbed acid base balance and dehydration when present Therefore treatment will vary with the underlying condition which produces alkalosis If due to excessive alkali ingestion obviously the alkali should be discontinued If the condition has reached the stage of tetany an intravenous injection of 500 to 1000 cc of 1 per cent saline solution repeated within an hour if necessary, will control the situation Forcing fluids by mouth will facilitate the excretion of the excess alkali in the blood An alkalosis produced by vomiting in which there is loss of chlorides and marked dehydration should receive an intravenous injection of 1000 cc of 1 per cent sodium chloride solution repeated every three hours so long as necessary Alkalosis due to overventilation of neurotic or central origin is relieved by rebreathing a 5 per cent carbon dioxide oxygen mixture

DISEASES OF THE DIGESTIVE SYSTEM

INTRODUCTION

THE great frequency of disorders of the digestive tract is due to the high incidence of primary *organic disease of these organs* and even more to numerous reflex or functional disturbances Gastro intestinal symptoms may be the initial or outstanding manifestations of such diverse diseases as scarlet fever intracranial tumor, pulmonary tuberculosis psychoneurosis or a senile depression It is thus impossible to separate gastro enterology from general medicine The newer developments in this special field however have been so important and have occurred so rapidly that a considerable degree of necessary and to a certain extent, desirable specialization has occurred Nevertheless the general practitioner is the first and only physician to meet and deal with the great bulk of the digestive disorders hence it is important for him to understand them well The *organic diseases* are of all types infections parasitisms intoxications deficiency states metabolic abnormalities benign and *malignant neoplasms, and others* The so called *functional disorders* are less tangible but no less real In general they may be 'reflex' toxic' emotional' or psychogenic" in origin It is very easy to quibble about names and definitions Perhaps a few simple examples will best serve to illustrate the meanings intended The nausea and vomiting of an intracranial tumor is obviously of central origin the nausea and vomiting of pregnancy is probably reflex although hormonal and emotional factors may be operative the emesis induced by ipecac and the diarrhea induced by castor oil are 'functional' although obviously attributable to a specific exogenous irritant the diarrhea of fear seems purely emotional in origin The gastro intestinal symptoms accompanying chronic states of fear anxiety tension and conflict are numerous bizarre and in one form or another ever present In practice the "functional' and the 'organic often co exist In the digestive tract it is particularly easy to argue if one wishes to do so for the interrelationship of the two, for the 'functional as a cause of the 'organic as for *instance in peptic ulcer* or ulcerative colitis In therapy, the functional may at times be entirely or almost entirely, disregarded usually it is of considerable importance and very frequently it is all important Not infrequently the organic may be disregarded The problem of the practitioner is to determine the cause of the patient s illness to cure the illness if possible and to prevent future illness

The *methods of examination* in digestive tract disease are the usual ones of medicine A good *history* is the first essential It should include an analysis of the distress peculiar to the acute attack or the chronic complaint with its relationship to the normal activities of life such as meal taking bowel habits menstrual periods exercise and so forth it should contain an inquiry into the function of other organs and systems the state of the appetite and the weight and it should include an evaluation of the individual in respect to his work his home his social relationships—in short a detailed appraisal not merely of the patient s symptoms but of the patient himself of the environment and of his emotional adjustment to the environment The *physical examination* is important but frequently not nearly as much so as the history

Laboratory procedures of all kinds may be important Those incident to any complete examination include complement fixation tests for syphilis erythrocyte and leukocyte counts hemoglobin determinations and urinalysis In addition the symptoms and findings may call for such investigations as a study of the spinal fluid careful appraisal of renal function chemical determinations of various constituents of the blood serum such as the carbon dioxide content the *p*H the chloride glucose urea nitrogen calcium cholesterol bilirubin or protein content and tests for the presence in the serum of specific

antibodies such as those for *S dysenteriae* or *B melitensis* The cost of these procedures is considerable it is neither necessary nor wise to order them routinely Judgment and knowledge are necessary in order to know when to obtain them and properly to understand and interpret them once they are made The same statement may be made with regard to the analyses more directly related to the digestive tract It is helpful to know whether the stomach secretes acid or not because of the extreme rarity of (a) pernicious anemia without achlorhydria and (b) benign ulcer with achlorhydria but emphasis on variations in gastric secretion as a cause of dyspeptic symptoms is erroneous The histamine test is simple to perform and may be a routine feature of the gastro intestinal examination in certain cases Similarly tests for the presence or absence of occult blood in the feces provide evidence for or against the diagnosis of gastro intestinal neoplasm The benzidine test employed on feces obtained after three days of a meat free diet is very simple and practical A careful microscopic examination of the feces especially those obtained after the administration of magnesium sulfate and *not* contaminated by barium bismuth or oil is important in instances of suspected parasitism A microscopic examination of the duodenal content obtained by so called duodenal drainage may disclose the presence of *Giardia lamblia* but these can usually be detected in the feces Other conclusions often reached from the results of duodenal drainage are of questionable value

Numerous tests of liver function have been described some are worthless some are helpful none is completely satisfactory The various dye methods usually give results roughly comparable to the retention of bilirubin present The tests dependent upon metabolic functions in the hepatic cells are of some value such as the hippuric acid test and the glucose and galactose tolerances Alterations in the constituents of the circulating plasma are often found and may denote impairment of hepatic function such as a low prothrombin content a low ester fraction of cholesterol or a low serum albumin not attributable to protein loss The colloidal gold and cephalin flocculation tests are dependent apparently upon qualitative alterations in the serum globulin resulting from disturbances in hepatic cellular metabolism

The *x-ray* is without question the most important method for the diagnosis of disease of the digestive tract The accuracy of skilled workers using the best equipment is phenomenal the reliability of untrained men using inadequate equipment is of course much less Errors consist of false positive diagnoses and of failures to find the lesion present Some of these errors are permissible for the method does have its limitations However there is a great need for more and better trained radiologists and for better machines Modern mucosal relief technic using so called spot films" with the fluoroscopically aimed exposure has greatly advanced the examination of the esophagus stomach duodenum and small intestine The air and barium double contrast films of the colon disclose in exquisite detail the finer alterations in the mucosa of that organ The methods perfected are splendid they must be used by trained workers they must be made more available The clinician however carries the final responsibility he must evaluate carefully all the evidence In the examination of patients with continued abdominal complaints whether mild or severe the roentgenologic examination particularly of the upper digestive tract should be omitted rarely if ever The cholecystogram and the barium enema while important are perhaps less essential as routine procedures

The *endoscopic methods* provide the only nonsurgical means for the direct inspection of the inner organs They rank in terms of the objective evidence provided second only to x rays Esophagoscopy is the most difficult of these procedures and the most hazardous it should be performed only by those properly trained and only when a definite indication exists Gastroscopy using the flexible instrument (Schindler) is a comparatively safe procedure but interpretation may be difficult Consequently it also should be carried out only by those well trained Proctoscopy is relatively safe requires the minimum of training and is of great value Benign and malignant neoplastic lesions of the rectum and rectosigmoid are very common are often beyond the tip of the examining finger and may be difficult to demon

strate roentgenologically The proctoscopic pictures of amebic dysentery nonspecific ulcerative colitis and lymphopathia venereum are usually quite typical The peritoneoscope is the newest of the endoscopic procedures and in trained hands seems to be of considerable value in selected cases

Two facts should ever be borne in mind by those dealing with chronic disorders of the gastro intestinal system first that more people die of neoplasm of the digestive tract than of any other system (in 1938 the deaths from cancer of the digestive tract and peritoneum comprised 47 per cent of the total cancer mortality) and second that many of these deaths could be prevented by earlier diagnosis and earlier operation

WALTER L. PALMER

DISEASES OF THE MOUTH

Infectious Diseases—The specific infectious diseases are accompanied by characteristic lesions in the mouth Tiny white spots surrounded by a red areola (*Koplik s spots*) are seen upon the inner surfaces of the cheeks and lips before the appearance of the rash of measles In scarlet fever enlarged fungiform papillae of the tongue protrude as scarlet points through the white coating causing the *strawberry tongue*

The *smallpox eruption* and *chickenpox* vesicles regularly appear upon the lips tongue palate and inner surfaces of the cheeks In about 7 per cent of cases of *typhoid fever* small ulcers appear upon the fauces

Mucous membranes are involved in all stages of *syphilis* Chancre of the lip or tongue appears as a sluggish painless ulcer with infiltrated base healing with slight deformity In the secondary stage the throat is injected and mucous patches appear on the tongue buccal surfaces and lips At the angles of the mouth condylomata occur Late in the disease gumma of the tongue begins deep beneath the middle of the dorsal surface and soon breaks down to form a sharply punched out ulcer The tongue is often shrunken smooth and harder than normal while the smooth atrophy of Virchow may be felt on the posterior surface Gumma of the lip is similar to that of the skin, gumma of the hard palate causes necrosis of bone and perforation Extending from the lips there may be rhagades or their scars

Tuberculosis is derived from milk, from tuberculous sputum or from extension of *lupus vulgaris* from the face The lesions are most frequent on the lips the edges of the tongue and soft palate Several small yellowish nodules appear at once ulcerate and gradually enlarge About the ulcer there are usually a few tiny nodules The discharge is thin and blood tinged and contains *tubercle bacilli* Healing is very slow

Yaws occasionally attacks the mucous membranes of the mouth late in the secondary stages and appears usually in the form of ulcers The characteristic frambesioid lesion has a tendency to profuse growth about the lips and nose *Gangosa* is a destructive ulcerative process which begins in the soft palate and slowly involves palate, nose lips and even the eyelids Recently it has been found that the causative organism is the same as that of yaws and responds to the same treatment

Rhinosporidiosis is due to infection by a phycomycete the *Rhinosporidium seeberi* which may be associated with cattle Lobulated masses of considerable size likened to a large cock s comb develop on the pharynx lips nose, eyelids and occasionally on the genitals and skin They must be cleanly excised preferably by electrocautery The native treatment—application of a mixture of lime and tobacco—*is said* to be effective

Espundia is the tertiary stage of American leishmaniasis Ulceration of the mucous membranes of the mouth proceeds to destruction of cartilage and bone and resulting deformity Hyperplasia may occur and then lobulated masses develop about the nose and lips *Verruca peruviana* of the cutaneous type occurs as profusely on the mucous membranes as upon the skin The red warty looking tumors usually ulcerate later *Foot and mouth disease* is transmitted from cattle Its rash occurs as freely on the mucous membranes as on the skin the vesicles in the mouth soon becoming superficial erosions which heal in a few days without scar *Leprosy* of the cutaneous type in nearly all cases develops in the mouth and on the lips

and pharynx The macule and the nodule are the usual clinical manifestations

Inorganic substances absorbed in small amounts for variable periods of time may cause lesions in the mouth

Mercury through occupational or therapeutic use causes the condition known as ptyalism Earliest symptoms are a metallic taste with soreness of the teeth upon chewing Later increased secretion of saliva swollen tender gums which *bleed easily swelling* of the salivary glands and a foul breath appear In extreme cases ulcers appear the teeth loosen and fall out and the jaw undergoes necrosis If mercury is discontinued when early symptoms are noted no trouble ensues With greater intoxication it is advisable to use an antidote Sodium thiosulfate is administered intravenously in doses of 0.3 to 1 gram at intervals of three days and careful attention is given to diet

Bismuth in the form of paste for the dressing of sinuses made surgeons familiar with its toxic effects With its current use in the treatment of syphilis the 'bismuth line is again commonly seen Located at the gum margin it is blue black but less sharply defined than the lead line *Less frequently* there may be blackish plaques of variable size on the gums or cheeks punctate or diffuse pigmentation of the soft palate blackening of the filiform papillae of the tongue and the veins beneath the tongue As a rule pigmentation disappears within three months after cessation of bismuth administration

Stomatitis develops in about one-tenth of the cases and its severity varies directly with the extent of pigmentation Gingivitis salivation and a foul breath are the mild manifestations With severe intoxication ulceration occurs about the third molars along the gum margin and in the floor of the mouth As infection develops anorexia and cachexia follow and fatalities have been reported

The use of a dentifrice and mouth wash of talc 85 per cent and sodium hexametaphosphate 15 per cent is reported to reduce the incidence of *stomatitis and even the pigmentation*

Iodine in any of its preparations may cause toxic symptoms Coryza is the most common but sometimes a coppery taste swollen mucous membranes soreness of the salivary glands and increased secretion of saliva follow its use Rarely with even minute doses sudden and alarming swelling of lips tongue and larynx may ensue Similar edema occurs with the *salicylates*

Radium—Intractable necrosis of the jaw is caused by ingestion of radioactive substances The radioactive material is deposited in the bones where it causes a condition *known as radiation osteitis Oral sepsis* is apparently responsible for the necrosis by adding infection to bone already the seat of disease Symptoms may not occur for several years after exposure The diagnosis is made during life by examination of the expired air for radium emanation using an electroscope or for the alpha particles by a scintillation screen No known treatment is curative possibly patients can be kept alive until the life period of mesothorium has expired

Dilantin (sodium phenylhydantoinate) used as an anticonvulsant in epilepsy causes hypertrophy of the gums particularly when there is poor oral hygiene Of slow onset and development the first symptoms are soreness *swelling and bleeding of the gums* but later these structures become firm and so much hypertrophied that the teeth are nearly covered and there is trouble in chewing Vigorous massage of the gums from the beginning of treatment and later gingivectomy in stages make possible the continued use of the drug

Gingivitis occurs in workers exposed to *chromium* it may follow the therapeutic use of *gold* salts of *ergoapiol* of *phenolphthalein* and it is one of the symptoms of poisoning by maize smut (ustilaginism)

Absorption of *lead* leads to gingivitis and the appearance of a blue black line at the margin of the gums *Silver* absorption results in bluish pigmentation of the mucous membranes while *arsenic* causes brownish stains of the mucosae of the cheeks or palate *Acetanilid* used habitually causes cyanosis of the lips

Diseases of the Skin—Many diseases of *the skin are accompanied by lesions of the* mucous membranes The more frequent are

Erythema multiforme in its recurrent attacks and various types of skin eruption may be accompanied by a bullous eruption in the

mouth The bullae soon become shallow ulcers which reveal no characteristic micro organism

Lichen planus often attacks the mucous membranes weeks before skin lesions occur In mouth and tongue the lesion is papular noninflammatory, feels somewhat rough and looks like mucosa to which silver nitrate has been applied The recurrent acute outbreaks the itching and the distribution and angularity of the skin lesions serve to make the diagnosis

Pemphigus in all forms is associated with bullous lesions of the mucous membranes which may appear in successive crops for weeks before there are any skin lesions Mouth bullae soon rupture to form shallow painful erosions which are covered with a diphtheroid membrane

Dermatitis herpetiformis (hydroa) is a chronic recurring inflammatory disease of the skin in which small vesicles occur in the mouth These rupture to form bright red ulcers which heal rapidly Intense itching is the outstanding complaint

The pinkish scaly eruption of *lupus erythematosus* is accompanied by shallow erosions of the lips buccal surfaces or tongue in about one fourth of all cases There are few subjective symptoms As healing occurs there is considerable atrophy with formation of a bluish scar The diagnosis is made from the characteristic skin lesion

Pseudocolloid (Fordyce s disease) of the inner surfaces of lips and cheeks occurs as numerous small yellow noninflammatory masses scarcely raised above the surface There are no symptoms and no treatment is required

Several clinical types of *lipoidosis* are accompanied by mouth lesions The simple *xanthoma* on tongue or cheek is common, less frequent are the lesions accompanying xanthoma tuberosum multiplex extracellular cholesterosis Gaucher s disease and the extensive infiltration of tongue and gums of lipoid proteinosis

Deficiency diseases are accompanied by characteristic lesions of the mouth Swelling soreness and bleeding of the gums occur early in *scurvy* In severe cases there is ulceration the teeth may fall out the salivary glands and tongue swell and hemorrhages occur beneath the mucous membrane of the palate In *pellagra* the mucous membranes are reddened denuded of epithelium and may be ulcerated The tongue and gums are swollen while the former is coated and bright red at the tip and edges *Pyridoxin* deficiency also causes a glossitis with a purplish red color Soreness of the tongue is one of the earliest symptoms of *sprue* The tongue is red the epithelium is lost the filiform papillae are swollen and there may be small vesicles or ulcers Anemia and the bulky fatty stool are characteristic *Riboflavin* deficiency causes redness and irritation of the lips fissures at the corners of the mouth much like perleche and a fine sandy desquamation of the nose

The *Plummer Vinson syndrome* is probably an iron deficiency There are chronic cheilitis glossitis and pharyngitis with resulting dysphagia and occasional choking spells There appears to be a special liability to mouth cancer Other features are the hypochromic anemia and koilonychia

Diseases of the blood and of the spleen cause mouth lesions

The red, engorged almost to bursting appearance of the mucous membrane of the mouth in *polycythemia* is very characteristic

Bleeding from the gums is seen in *jaundice* from any cause but is frequent in hypertrophic cirrhosis and hemolytic icterus It also occurs in *Banti s* and *Gaucher s diseases* In *idiopathic aplastic anemia* or in the secondary types from *benzol poisoning* or *chronic infection* petechial spots are seen and bleeding from the gums occurs while in *purpura hemorrhagica* bleeding from mucous membrane of the mouth may be serious

Pernicious anemia in its early stages is accompanied by soreness with patchy redness of the tongue and buccal mucosa In the late stages the tongue becomes pale and flabby with marked atrophy of the epithelium Areas of slaty pigmentation are seen in some cases on the cheeks lips and edges of the tongue Pigmentation of the mucous membrane of the mouth occurs in disturbances of the chromaffin system such as Addison s disease and retroperitoneal growths and is associated with small papillomatous growths in *acanthosis nigricans*

In leukemia of either type there may be bleeding from the gums or the first sign

of the disease may be an intractable hemorrhage from the socket of a recently extracted tooth Late in the chronic forms or at the onset of the acute forms acute stomatitis frequently develops and progresses to ulceration Gingivitis and ulceration occur in *agranulocytosis*

SAMUEL BRADBURY

DISEASES OF THE GUMS TONGUE, LIPS AND TEETH

Halitosis —In some instances halitosis is caused by evident local oral or nasal pathology In other cases however according to Crohn and Drosd malodorous breath is due to indigestion faulty metabolism of fats, and may be corrected by a low fat diet usually with the help of daily saline laxatives

Oral Sepsis —The common sources of oral sepsis are *alveolar abscess* and *pyorrhea* rarely there are infected *radicular* and *dentigerous cysts* An alveolar abscess results from caries of a tooth destruction of the pulp and ascending infection of the root canal The abscess at the root tip points through the gum (a gum boil) or it may be chronic and cause no local symptoms Abscess may result from a pyorrheal pocket the tooth remaining vital

Pyorrhea starts with inflammation of the periodontal membrane and progresses to rarefying osteitis of the alveolar process osteitis may occur without external sign of infection Sepsis results from absorption of toxins and bacteria Devitalizing influences such as malocclusion badly fitted appliances and dental calculus account for some cases but the majority appear to be caused by a chronic systemic disorder

Pyorrhea and alveolar abscess are frequent and are potential sources of trouble Often there are no symptoms there may be however a subnormal health level and rarely such serious consequences as chronic arthritis infection of the heart valves or kidneys or of the blood stream

Teeth —The Research Council of the American Dental Association in summarizing the opinions of observers from all parts of the world concludes that the causes of dental caries are not understood It is generally stated that caries is a bacterial disease with typical lesions coming in characteristic places and with the initiating factor acid destruction of enamel But why there is more caries in women than in men why primitive man has so little until he adopts civilized habits and why some persons may with impunity neglect oral hygiene is not explained It is acknowledged that a method of prevention is not yet achieved and it is held that such may be expected only through diet At present the sweets are generally held to be the most deleterious food factor

Mottled enamel is characterized by a chalky blotched appearance of the permanent teeth which may later become brown and is caused by fluorine in drinking water Such teeth are far less liable to caries and it has been shown that fluorine in amounts not sufficient to cause mottling will radically reduce the incidence of decay Mottled enamel occurs all over the world and in nearly 400 localities in the United States

Stomatitis —*Catarrhal Stomatitis* —The causes of catarrhal stomatitis are digestive disturbances traumatism by hot or highly seasoned food and the excessive use of tobacco There are swelling redness and tenderness in the gums cheeks and lips The tongue is coated there is salivation and a bad taste Infants refuse to eat and may have slight fever and diarrhea The disease lasts from three days to a week Mild mouth washes should be used frequently or in infants gently applied on pledgets of cotton

Aphthous stomatitis (*herpes simplex fever blister canker*) is an acute nonimmunizing infectious disease caused by a filtrable virus which is latent in many people It is activated by infections such as pneumonia epidemic meningitis and malaria by digestive disturbances and during the menses The disease occurs frequently in some families during puberty and in women Small vesicles singly or in groups appear upon the lips labionasal fold under the tongue or at the base of the alveolar process In the mouth the vesicle ruptures and forms an ulcer 1 to 3 mm in diameter covered with yellowish exudate and surrounded by a hyperemic zone There are pain salivation slight fetor and healing in five to ten days Local treatment consists in mild mouth

washes and the application of camphorated phenol Smallpox vaccine is said to prevent the recurrence of this troublesome disease Four vaccinations are made by the multiple pressure method at intervals of two weeks unless a take occurs then the take is allowed to subside and the series is resumed

Ulcerative stomatitis is uncommon and develops in children more than four years of age or in adult inmates of institutions or jails Local devitalizing factors such as carious teeth and accumulations of tartar play a role in its etiology and it may be that institutional epidemics are caused by deficient diets

The disease begins at the margin of the gum with swelling redness and oozing of blood upon slight manipulation usually in front of the lower incisors or on the outer side of the molars The inflamed area becomes necrotic ulceration spreads along the free border of the gums to the cheek and lower side of the tongue and is covered with a yellowish adherent slough The nearby lymphatic glands are enlarged and tender there is marked salivation coating of the tongue with slight swelling and a putrid odor to the breath In the worst cases ulceration may extend to the alveolar process and cause loss of teeth and necrosis of bone A few cases in children progress to noma An exanthem may occur and be mistaken for measles (Osler)

Sufficient food including vitamins must be given to children by gavage if necessary preferably in the form of cool liquids or soft solids Carious teeth and necrosed bone should be removed Mouth washes of potassium permanganate (1 8000) should be used frequently The ulcers may be touched with silver nitrate

Gangrenous Stomatitis (Noma Cancrum Oris) —This disease is essentially a rapidly spreading gangrene which occurs in debilitated children two to five years of age usually after one of the infectious diseases

The first manifestation is an extremely offensive breath Upon the buccal surface gum or inner side of the lip is found a small ulcer covered with gray or black slough which spreads both laterally and in depth In a remarkably short time the skin over the cheek becomes brawny then red and tense finally black and broken Gangrene rapidly destroys a large portion of one side of the face and attacks the tongue palate and gums Pain and fever are not marked the child is prostrated and death occurs in five to ten days The few children who recover are markedly deformed Bronchopneumonia abscess of the lung and severe diarrhea are complications

Treatment consists in early and thorough excision of the gangrenous area by the electrocautery If the child recovers plastic repair of the face may follow Diphtheria bacilli have been cultured from the gangrenous area and whenever present large doses of antitoxin should be administered

Ulceromembranous stomatitis is the name given to infection of the gums by the fusiform bacillus and spirochete described by Vincent It is the 'trench mouth of soldiers Epidemics of the disease occur and fatalities are reported

The accompanying symptoms and appearance of the lesion are similar to those of ulcerative stomatitis although isolated patches upon the buccal surfaces tongue and palate occur The infection is obstinate difficult to eradicate and recurs frequently Diagnosis is made by examination of smears from the infected gums

Treatment is difficult and requires pains taking attention to detail It is important in all cases that the food be nutritious and especially rich in vitamins In ordinary cases after the slough is removed a paste of sodium perborate powder is applied to the ulcers and held in place five to ten minutes After removal of the slough usually by means of half strength hydrogen peroxide solution the mouth is packed with cotton rolls the ulcers dried and chromic acid in 5 to 10 per cent aqueous solution is applied they are then allowed to dry and are covered with compound tincture of benzoin Or after similar packing and drying freshly activated zinc peroxide or an 8 per cent solution of zinc chloride or a paste of finely powdered copper sulfate may be used The latter particularly must be carefully rinsed off before removal of the packing Another local application is neoarsphenamine 10 per cent in glycerin Neoarsphenamine intravenously in doses of 0 3 Gm for adults is used but is not effective

Parasitic stomatitis (thrush) is due to a fungus of the class of Hyphomycetes known as *Oidium albicans* It infects the mouths of debilitated infants or those whose mucous membranes have been injured by violent cleansing or by stomatitis It is seen occasionally in adults after a severe infection or in the late stages of chronic illnesses

The infant refuses to nurse or has difficulty in swallowing There may be diarrhea with irritation of the buttocks The mouth appears dry and scattered over tongue gums cheeks and lips are small white patches which look somewhat like milk curds and can be removed only with difficulty leaving an hyperemic area which may bleed slightly The diagnosis is made by examination of a fresh specimen The usual attack lasts but two or three days Occasionally the infection may extend to the esophagus and pharynx and rarely to the trachea lungs and skin of the fingers and face Systemic infection has been reported

Infected areas should be painted twice daily with 1 per cent aqueous solution of gentian violet

Dermatostomatitis (Ectodermosis Pluriorificialis) is a rare disease of children and young people the worst result of which may be blindness It is characterized by chill fever and headache profuse salivation conjunctivitis development of vesicles on the lips tongue and cheeks and later erythematous or petechial lesions on the hands

Ludwig's angina is a streptococcal infection of the floor of the mouth Onset is acute with marked constitutional symptoms Swelling under the jaw extends into the neck pushing the tongue upward and the hyoid bone down The disease is frequently fatal *Treatment* consists of free incision and drainage Tracheotomy is often necessary The sulfonamides are effective *if there is time for sufficient dosage*

Bednar's aphthae are small ulcers upon the posterior part of the hard palate which are caused by unnecessary roughness in cleansing the infant s mouth or from pressure of too long a nipple

Riga s disease develops in infants after the eruption of the lower incisors It is especially common in Italy There is an indurated grayish area on the frenum of the tongue which may ulcerate later The affection may last for months but finally disappears Treatment is unsatisfactory The indurated area may be excised or tincture of iodine may be applied periodically

Periadenitis mucosae necrotica recurrens (aphthae resistentia) is possibly based upon endocrine disturbance At intervals pin head size painful nodules appear in the mouth and upon the genitalia enlarge ulcerate and resolve in about ten days Sutton advocates sulfathiazole in large doses

Other Types of Stomatitis —The frenum of the tongue may be ulcerated from pressure upon the lower incisors during attacks of whooping cough

Stomatitis due to infection by the *diphtheria bacillus* and the *gonococcus* is rare

Lips —*Harelip* is a congenital deformity caused by failure of the frontonasal plate to unite with the lateral process In the more severe grades the palate is commonly cleft. If the child nurses properly operation may be postponed to the third month but if there is difficulty it is advisable to operate while the infant is in relatively good condition

Macrocheilia is usually caused by *lymphangioma* There is gradual painless enlargement usually of the upper lip sometimes with attacks of acute inflammation Radiotherapy has been successfully used in treatment The less common cause is hypertrophy of the mucous glands known as *cheilitis glandularis apostematosa* The lower lip is more commonly involved there is excess secretion of mucus and the enlarged glands may suppurate Each gland must be removed separately

Cheilitis —*Acute cheilitis* (eczema of the lips) is caused by wind cold sunburn the lip stick and the drugs contained in some tooth pastes The vermilion border of the lips is inflamed crusts and often fissures occur It may be necessary to hold together the edges of fissures with narrow strips of adhesive plaster but usually removal of the cause and the application of zinc oxide ointment suffice

Chronic cheilitis (keratosis labialis) has much the same etiology and treatment as leukoplakia and is discussed under that heading

Perlèche (cheilitis migrans) is an infectious disease usually seen in children Small

white patches or vesicles form at the corners of the mouth, later, fissures form and are quite painful Tinnerud has isolated fungi in many cases either cryptococcus or monilia Nutrition must be improved, the mouth kept scrupulously clean, the lesions touched with 2 per cent aqueous gentian violet solution and the area covered with zinc oxide ointment

Carbuncle of the upper lip may cause septic phlebitis of the facial vein with progressive involvement of the ophthalmic vein and cavernous sinus A small pustule with a wide zone of infiltration rapidly enlarges and breaks down There is fever and prostration Incision or excision are contraindicated In the early stages wet applications of boric acid are indicated

Tongue—Anomalies are *scrotal tongue* which is commonly seen and *bifid tongue* which is rare Defective development of the anterior portion produces a condition known as *tongue tie*

Macroglossia results from congenital lymphangioma There is difficulty in speech and in swallowing and if the tongue be of such size that it protrude constantly the external part becomes dry and fissured Gradually increasing enlargement is caused by growth of the lymphangioma and by repeated attacks of inflammation Protruding portions of the tongue are excised and the remaining part subjected to radiotherapy Enlargement of lesser degree may be treated by radiation alone

Geographic tongue is seen in children and in adults One or more small white or yellowish elevations appear gradually enlarge and desquamate in the center leaving red patches with broad white circular outlines The disease is obstinate and treatment is unsatisfactory

Hairy tongue (*black tongue*) occurs in adults A brown or black patch on the posterior dorsal surface of the tongue appears to be composed of coarse hairs about 1 cm in length They are hypertrophied filiform papillae and may readily be broken off There is no discomfort There is no agreement as to the causative organism The patch may disappear spontaneously to reform later A simple mouth wash should be prescribed

Median rhomboidal glossitis is a diamond shaped red irregularly surfaced patch on the upper midsurface of the tongue anterior to the *circumvallate papillae* It should not be confused with cancer

Acute glossitis may follow burns bites or *other injuries* or may develop during an infectious disease such as smallpox or typhoid fever Usually there are high fever salivation pain which is referred to the ears and swelling of the tongue The neighboring lymph glands are enlarged The tongue should be incised and cold applied

Burning tongue (*glossodynia*) is encountered in women of middle age With two exceptions the causes are obscure First is the electrogalvanic discharge which is said to occur between dissimilar dental fillings It results in complaints of tingling and burning of the tongue or cheek a salty taste, occasional nerve shocks and an erosion which will be located near the positive end of the arc Second is the *temporomandibular joint syndrome* (Costen) in which occur headache in the occiput and postaural regions deafness and tinnitus and burning of the tongue Through loss of the molar teeth and atrophy of the alveoli undue strain is thrown on the articulation between mandible and temporal bone with resulting irritation of the auriculotemporal nerve The complaints are alleviated by a properly built up denture which will restore the original line of the bite'

Moeller's glossitis is a superficial inflammation in which irregularly shaped very red patches appear on the tip or sides of the tongue There is burning or pain and sensitiveness to hot or spicy foods The condition is obstinate Nonirritating food and mild mouth washes are advised

Leukoplakia buccalis (*smoker's patch*) and *keratosis labialis* are seen in adults of middle age more than 90 per cent of the cases in men There may be but one or two small patches or the disease may involve most of the mucosa of the mouth and tongue Recent lesions are thin often crinkled and pearly looking older *ones* are creamy white and thick and will desquamate from time to time leaving a beefy red base Advanced patches are *indurated* become fissured or papillomatous and are associated with dryness of the mouth The pathologic change is essentially keratiniza

tion of the mucosa and sclerosis of the derma it is a defense mechanism

The cause is chronic irritation, the producing factors in order of importance are tobacco used in chewing or in a pipe carious or infected teeth the electrogalvanic discharge between dissimilar dental fillings or appliances highly spiced food and betel nut chewing In leukoplakia of the tongue 30 per cent of the patients have had syphilis it is not a factor in keratosis labialis or in leukoplakia in other areas (Sturgis and Lund) In their cases cancer of the tongue, lip or cheek developed twelve times as frequently as among the average population

Early lesions usually disappear upon cessation of irritation The patient must stop using tobacco hot or highly spiced food concentrated alcoholic drinks caustic drugs and the tongue scraper The dental mechanism should be carefully supervised and a mild mouth wash prescribed The thick creamy white lesions and the papillomatous or fissured lesions are dangerous and are best treated radically Excision with the electro cautery gives better results than radiation but both may be used Patients with a positive Wasserrmann reaction should receive antisyphilitic treatment

Tumors and cysts about the mouth may be of any variety

Epulis is a fibrous tumor of the gum It is soft usually pedunculated and may be lobulated Frequently it grows opposite the roots of carious teeth The mucous covering is easily injured and ulceration results Treatment is excision

Ranula is an obstructive cyst of the mucous or salivary glands under the tongue A translucent fluctuating usually painless mass is seen on one side under the anterior part of the tongue It should be excised

Torus palatinus an elongated hard smooth or nodular mass in the roof of the mouth is an exostosis of the palatal processes of the maxillae There is a familial tendency the mass usually appears during adolescence and gradually enlarges It does not become malignant but may assume such proportions as to disturb speech or interfere with proper fitting of a denture The bony mass is removed with chisel or dental burr

Cancer about the mouth causes 3 to 6 per cent of all cancer deaths 85 per cent of cases are in males most are seen after sixty five years of age, the rise in incidence beginning at forty five but there are cases in patients less than 30 years of age The lip is most frequently diseased then tongue and cheek there may be multiple tumors Predisposing causes are leukoplakia oral sepsis rough teeth or dental appliances use of tobacco fissures and scars and overexposure to sunlight

An indolent ulcer a papillomatous or nodular tumor, or infiltration about a fissure must be viewed with suspicion Early diagnosis is important Biopsy with the electrocautery knife confirms the diagnosis denotes the degree of malignancy and determines the radiosensitivity of the tumor Tumors of embryonal type metastasize early and are more sensitive to radium

Cancer when it starts is a local disease and is curable Its care is a surgical problem but the mutilating operation has been largely superseded by radiotherapy Radium is preferred for the local lesion and is applied by means of heavily filtered containers attached to a molded plaque for surface application or by the implantation of radium needles or radon seeds

Recovery depends upon the type and location of the tumor and the presence or absence of metastasis The best recovery rates are with cancer of the lip the lowest with cancer of the cheek The experience of Massachusetts is illuminating In all cancer cases six months or more had elapsed from the first symptom to consultation with a physician then proper treatment was not instituted for at least another six months

DISEASES OF THE SALIVARY GLANDS

The secretion of the salivary glands may be increased or diminished The normal twenty four hour amount in the adult is between 1 and 1.5 liters, the curve of output rising sharply during meals

Salivation (*Sialosis Sialorrhea*) —A true increase is known as salivation and may amount to a daily output of as much as 10 liters although the average amount is be tween 3 and 4 liters

The causes of salivation in the order of frequency are

1 Drugs or poisons, such as mercury, iodine tobacco, bromides arsenic, potas sium chlorate pilocarpine copper and bis muth

2 Local inflammation from any form of stomatitis except thrush, from pyorrhea and alveolar abscesses, and from such diseases as scurvy, sprue purpura and the anemias

3 Local irritation from jagged teeth badly fitting dental appliances teething ranula epulis and salivary calculus

4 Infectious diseases, especially smallpox and rabies

5 Reflex stimulation from the stomach pancreas liver and uterus Salivation is espe cially frequent in diseases of the stomach early in pregnancy and occasionally is an early symptom of ovarian cancer

6 Diseases of the nervous system such as seasickness and car sickness hysteria and migraine and the more serious organic dis eases such as irritation of the *chorda tym pani* usually with paralysis of the seventh cranial nerve degenerative lesions of the basal ganglia as in *paralysis agitans* and *en cephalitis lethargica* irritation of the vege tative system *tic douloureux* and *tabes* with salivary crises

7 Idiopathic cases in which no cause can be found Most cases develop after shock or severe emotion, there is an acute onset variable duration and sudden cessation

Symptoms vary, but when large amounts of saliva are swallowed indigestion and vom iting ensue In many cases the speech be comes thickened and the taste disordered

Treatment is that of the cause Atropine controls excessive salivation and bromides allay nervous symptoms Radiation of the salivary glands is effective in reducing secre tion but may cause dry mouth

Xerostomia (*Oligosialia*) is deficient se cretion of saliva The severity of the condi tion varies it may be apparent only when eating or there may be such deficiency that mouth and tongue are completely dry Some times there is also dryness of the conjunc tivae and the nasal cavities

The local infection thrush and the fevers are accompanied by dry mouth The drugs belladonna and opium cause deficiency of secretion Mild degrees of xerostomia accom pany the dehydrating diseases such as di abetes mellitus diabetes insipidus cholera and chronic nephritis X ray therapy of the facial regions may result in permanent de ficiency of secretion But the reasons for severe types of xerostomia are obscure, the unusual cases occur in women of nervous temperament without other signs of ill health It is suggested recently that some cases of xerostomia are instances of avita minosis

The salivary glands may appear to be normal or they may be swollen and the ducts full of thick mucopus In severe cases the tongue lips and buccal surfaces become dry shiny red and fissured and the conjunc tival sacs contain thick ropy secretion

Treatment is unsatisfactory A glycerin mouth wash is useful Pilocarpine may stim ulate the salivary glands A prolonged course of vitamin B complex or nicotinic acid is worth a trial The teeth require careful su pervision

Inflammation of the salivary glands may be acute or chronic In any type except that following calculus the parotid gland is most often involved

Acute Inflammation —Aside from mumps acute inflammation (parotid bubo) occurs as a complication in several diseases These

are of three distinctive groups acute general infections such as typhoid and typhus fever and pneumonia, injury or disease of the abdominal or genito urinary organs, or after operation upon these structures diseases which interfere with the secretion of the salivary glands such as obstruction of the ducts facial paralysis or conditions which cause dry mouth

As a rule a single parotid is inflamed The onset is sudden with increase of the fever and toxic symptoms already present The gland swells becomes tense and tender, there is pain which is referred to the ear and interference with swallowing The swelling rapidly increases the overlying skin soon becomes red and shiny and in a few days fluctuation is present The infectious agent is usually Staphylococcus aureus The disease is serious and carries a high mortality

TREATMENT —The prevention of acute parotitis consists in scrupulous cleanliness of the mouth and the prevention of dehydration in postoperative and febrile conditions by the maintenance of a high fluid intake either oral or parenteral If inflammation develops an ice bag or a poultice should be applied Early x ray therapy reduces toxemia lessens suppuration and lowers mortality Should pus develop the gland should be incised with care to avoid the facial nerve and the large vessels

SYPHILIS may cause acute or gummatous inflammation Sixty five cases have been reported 22 occurring in the early stages 37 in the late stages and 6 in congenital syphilis The parotid was involved alone in 53 cases and 5 cases with other salivary glands There is gradually increased swelling and salivation but not much pain or tendency to suppuration Both the early and late forms respond to the usual antiluetic medication

Chronic inflammation is more frequently multiple than acute and may affect all the salivary glands The usual causes are mumps syphilis inflammation of the throat prolonged exposure to mercury iodine or lead and chronic nephritis Salivary calculi especially those lodged in the ducts may cause chronic infection As a rule the parotid glands are infected in glass blowers who have gaseous tumors There is impaired secretion and usually slight swelling which varies in degree from time to time

The possibility of calculi should be ruled out by examination and by x ray Otherwise the treatment is that of the assigned cause

Salivary calculi (*sialolithiasis*) develop in men about twice as frequently as in women Bacterial infection stricture from wound or inflammation and possibly foreign bodies are the usual preceding conditions In two thirds of the cases the calculus forms in the submaxillary gland or its duct The stones are composed mainly of calcium oxalate with smaller amounts of organic matter carbonates phosphates and magnesia They vary in size from a diameter of 3 to 30 mm The largest are found in the glands and are usually round or irregularly lobulated duct stones are of small diameter and oval

A calculus in the gland causes no *symptoms* unless it sets up inflammation but the patient may notice unusual swelling before this occurs Duct calculi produce symptoms when they cause obstruction There is sudden pain often of colicky nature usually felt in the floor of the mouth and relieved by a gush of saliva The swollen gland is readily felt and quite tender The stone may be found in the duct by palpation An x ray picture taken to avoid the mandible demonstrates the calculus

The *treatment* is excision

Uveoparotid fever is characterized by firm painless enlargement of the parotids with inflammation of both uveal tracts and low grade fever of several months duration Often there are bilateral facial paralysis deafness and tinnitus and in some cases polydipsia polyuria polyneuritis xerostomia glossodynia enlargement of other salivary glands and of the lacrimals and general lymphadenopathy with splenomegaly As this clinical syndrome is more carefully observed it is clear that it has many of the clinical features of and should be classified with Sarcoidosis

The etiological agent is unknown with negative tuberculin tests absence of acid fast organisms and general tendency to recovery it is probably not the tubercle bacillus Most patients with uveoparotid fever return to health but the uveitis leaves permanent visual defects

Mikulicz's syndrome, first described in 1888 is a symmetrical enlargement of first, the lacrimal then the salivary glands Cases

have been seen in which there is splenomegaly and local or general lymphadenosis some with normal blood, others with changes in the blood which are typical of chronic lymphatic leukemia A very few cases have been seen to change gradually from simple to more severe types, in others, there has been subsidence of the swelling after an acute infection The usual histology of excised tissue *is that of lymphoma After complete* extirpation of the glandular masses there is no tendency to recurrence nor to involvement of the lymphatic structures

The swelling progresses very gradually involving first the lacrimal glands then the parotids, submaxillaries, and the sublinguals In some cases accessory glands on the hard palate and the tongue share in the enlargement The picture is not always complete, the lacrimal glands may be involved alone or they or any one or more of the salivary glands may escape The glandular masses are firm smooth painless, not tender and not adherent to the surrounding structures

The patients complain of their appearance and of difficulty in vision caused by ptosis of the eyelids and interference with the movement of the eyeballs Excretion of saliva is *usually so* deficient as to cause difficulty in mastication and deglutition and diminution of excretion of the lacrimal glands causes irritation of the conjunctiva As a rule the *patient remains in good general* health

Of two male patients with typical Mikulicz's *syndrome* one had *general lymphadenosis* with biopsy showing lymphosarcoma the other recovered upon antiluetic medication A young woman with marked bilateral swelling of the parotid and submaxillary glands had also symptoms of hypothyroidism, the swelling disappeared upon thyroid medication A few cases are due to syphilis or tuberculosis but most can be ascribed to no definite cause Men are more frequently affected than women and while the disease occurs in children the usual age of onset is between twenty and forty years

Treatment —The internal administration of arsenic and potassium iodide has proved a satisfactory form of treatment in most cases Exposure to the roentgen ray has been successful Surgical removal of affected glands is advisable in selected cases

Tumors —Almost any type of tumor either benign or malignant, may develop in the salivary glands, and in 75 per cent of the cases the parotid is involved Forty two of fifty proved malignant tumors were found to be in *nearly equal proportions mixed* tumors or carcinoma or sarcoma, of twenty histologically benign tumors fifteen were of the mixed type

The tumor is first noticed as a small nodule in the gland tissue which may remain quiescent for years, then enlargement begins either slowly or rapidly The tumor may feel very dense or quite soft according to the type of the predominant tissue, it is rarely tender usually smooth but sometimes lobulated

The best *treatment* is early and complete excision followed by exposure of the area to the roentgen ray Local recurrence is frequent The recurrent growths are usually more malignant Metastasis is unusual

DISEASES OF THE PHARYNX

Acute Pharyngitis (*Sore Throat Angina Simplex*) —INCIDENCE —Acute inflammation of the mucous membrane of the pharynx occurs in individuals whose *general* condition is poor or whose habits of life are faulty The incidence is higher in spring fall and winter than in summer

This disorder is *frequently the* initial or early symptom of some acute infectious disease such as acute coryza scarlet fever measles or influenza Early secondary syphilis of the pharynx *often resembles* acute pharyngitis

Etiology —Exposure to drafts and chilling of the body after violent exercise are frequent causes *Local allergic reactions* to certain fruits such as grapes strawberries or

grapefruit sometimes cause a condition resembling acute pharyngitis

Symptoms.—The disease may start with a slight cold or more frequently with a sensation of chilliness This is followed by dryness in the throat and irritation in the nasopharynx Soon the throat becomes painful and swallowing is difficult Examination of the throat at this time reveals a mucous membrane which is red swollen and covered with whitish mucus The general constitutional symptoms of a mild febrile condition are present In very mild cases the temperature may not rise at all Acute pharyngitis lasts from one day to two weeks and is usually self limited Not infrequently however the infection extends upward into the nasal cavities or downward into the larynx and trachea

Diagnosis—The fact that for some time (twenty four to seventy two hours) it may be the only local symptom of an acute infectious disease must be especially borne in mind when marked congestion of the throat is associated with severe general symptoms The condition in itself is not difficult to recognize

Treatment—Therapeutic measures should be of such a character as not only to hasten recovery but also to prevent recurrence of the disease The general physical condition of the patient must be determined the habits regulated suitably and any predisposing factors such as deviation of the septum infection of the sinuses or tonsils and dental pathology eliminated At the onset of an attack a laxative (preferably castor oil) should be administered and the patient put to bed Patients with fever ought to remain in bed until the temperature falls to normal those in whom the disease is afebrile may get up after the first twenty four hours

For local treatment there is nothing more satisfactory than irrigation of the throat with a solution of sodium bicarbonate (1 teaspoonful of soda in 1 quart of water) either hot or cold This may be supplemented by the application of an ice collar or cold compresses to the throat Local antiseptics are not beneficial in the acute stage and should be avoided A soft simple diet is desirable

If a hemolytic streptococcus be suspected or proved to be an etiologic factor in this condition the administration of sulfadiazine may cut short the disease If drugs of this type are used throat irrigations must be limited to normal saline solution Daily blood counts and urinalyses should be made It is usually advisable to hospitalize the patient

Chronic Pharyngitis (*Chronic Sore Throat*) —This is usually a disease of adults It frequently develops in individuals compelled to work in dusty unhygienic surroundings and in those who use the voice improperly and to excess Habitual alcoholics and smokers are also disposed to the disease The condition is often associated with general systemic abnormalities such as gout rheumatism and certain chronic diseases of the circulatory and respiratory systems

Types of the Disease—Chronic pharyngitis is of three types—the hypertrophic the atrophic and the chronic granular type The *hypertrophic type* is characterized by general thickening and congestion of the mucous membrane of the pharynx which is thereby rendered velvety in appearance The *atrophic type* is probably a late stage of the hypertrophic and is evidenced by abnormal thinness of the mucous membrane which is whitish glistening and at times wrinkled In the *chronic granular form* (clergyman s sore throat) the hypertrophic changes are particularly marked in the lymph follicles of the posterior pharyngeal wall and on the lateral wall behind the posterior pillars of the palate

Symptoms—The symptoms are a constant sense of irritation or fulness in the throat the dropping of mucus from the nasopharynx or its collection in the throat and at times difficulty in swallowing Some patients cough and develop the habit of clearing the throat

Complications—The chronic inflammation not infrequently invades the eustachian tube and middle ear so that deafness ensues Subjects of the disease are susceptible to laryngitis and inflammation of the trachea and bronchi

Diagnosis—Examination of the throat and nasopharynx with either direct or reflected light permits easy diagnosis of chronic pharyngitis In the granular type the rounded masses of lymphatic tissue are visible in the postpharyngeal wall and be

hind the posterior fauces of the palate In the atrophic form the mucous membrane is seen to be pale and glistening and at times covered with brownish crusts Coakley says that the cicatricial tissue left by an old syphilitic, tuberculous, or lupoid ulcer may at times be mistaken for atrophic pharyngitis but that this tissue has a white puckered appearance different from that of the mucous membrane of atrophic pharyngitis

Prognosis—The symptoms of chronic pharyngitis, while annoying are not incompatible with fair general health

Treatment—The treatment of this condition is both local and general The *general measures* consist in making the general health as good as possible Alcohol and tobacco should be forbidden and the patient taught to use the voice properly and not to excess Infected tonsils should be removed and any abnormal condition in the nose corrected, surgically if necessary All dental pathology should be eliminated Aside from irrigation of the nose and throat with alkaline solutions to remove tenacious crusts and mucus *local treatment* is best performed by the specialist The results are apt to be discouraging The success of treatment depends on the duration of the disease and on the possibility of relieving the underlying predisposing cause

Retropharyngeal Abscess—A retropharyngeal abscess is an accumulation of pus in the submucous connective tissue of the pharynx

Etiology—This occurs most frequently in infants and children between six months and four years of age, but, occasionally has been seen in adults The incidence is high in the apparently healthy infants of the poor Coakley states that tuberculosis rickets and inherited syphilis are predisposing factors Occasionally the disease is secondary to tuberculosis of the cervical vertebrae

Morbid Anatomy—The abscess is usually due to a streptococcus infection of the retropharyngeal lymph nodes in the submucous connective tissue of the pharynx These glands enlarge and later break down and form an abscess The pus may burrow beneath the mucous membrane so that at times a large abscess develops which seriously interferes with laryngeal function

Symptoms—The onset of a retropharyngeal abscess is manifested by fever irritability, and crying These symptoms are soon followed by difficulty in swallowing and refusal of the infant to nurse or take the bottle The cry at times is of a peculiar quacking character, described by Regnier as "le cri de canard" Dyspnea may occur and with the cough produce a syndrome resembling that of croup The temperature may be high, and, on account of the inability to swallow, emaciation is at times rapid and extreme If untreated the abscess may rupture spontaneously during sleep and cause death by suffocation or produce suffocation and fatal inanition without rupture When the lesion is not severe there may be no apparent symptoms except those of nasal obstruction and it is discovered only during the routine digital examination for adenoids

Diagnosis—The diagnosis of retropharyngeal abscess is usually easily made by inspection or palpation If the mouth is opened with a tongue depressor a smooth oval swelling is visible on the posterior wall which pushes forward the palate and uvula By digital examination this is found to be smooth and elastic and fluctuation is often easily obtained Symptoms of croup must be carefully distinguished from those of a retropharyngeal abscess

Prognosis—If the abscess is evacuated early recovery is usually good but if the patient is first seen in the later stages of the disease when dyspnea and prostration are marked death may ensue even after prompt draining of the lesion Tuberculous abscesses and those which follow vertebral caries are apt to end less favorably

Treatment—The only treatment is early incision to permit free drainage Most abscesses can be opened suitably through the mouth when the child is held by the nurse with the head lower than the body and the mouth wide open The incision should be made through the mucous membrane in the median line beginning opposite the larynx and passing upward toward the palate It is necessary to guard the blade of the scalpel with the finger or a piece of adhesive tape about ¼ inch from the point Care should be taken to avoid injury to the soft palate When the pus ceases to flow from the mouth

and nose the abscess should be gently pressed with the finger to remove any purulent material which may remain Since the cavity sometimes refills and must be redrained it is desirable to watch the child closely for a few days after this operation If dyspnea and weakness place the patient in danger speed is necessary, but under ordinary conditions there is no need of performing the operation very rapidly If a retropharyngeal abscess is suspected to be tuberculous in origin secondary infection is best avoided by external incision along the anterior border of the sternomastoid This procedure should not be performed by the general practitioner After evacuation of the abscess measures should be employed to restore the child to its normal condition Life in the open air and the administration of tonics such as cod liver oil iron and vitamins are desirable Usually the relief after evacuation is immediate

Angina Ludovici (*Ludwig s Angina Cellulitis of the Neck*) —Johnson has described angina ludovici as a more or less violent purulent and sometimes gangrenous inflammation of the tissues occupying the submaxillary region of the neck The characteristic symptoms are those of severe sepsis the formation of a hard tense brawny swelling in the submaxillary region great pain difficulty in speaking and swallowing and sometimes cyanosis and dyspnea caused by pressure on the larynx or by swelling and edema of the throat If unrelieved by early incision *the whole side of the neck becomes* red and hard the constitutional symptoms threatening and the local symptoms of interference with respiration alarming This condition is usually secondary to violent infection of the throat or tonsils or teeth usually by a streptococcus occasionally by a staphylococcus The prognosis is grave and the practitioner should seek early the advice of a competent surgeon

In addition to the treatment outlined above the administration of sulfadiazine is probably indicated

Neuroses of the Pharynx —Neuroses of the pharynx are motor and sensory The most common *motor neurosis* that known as *globus hystericus* is a spasmodic action of the motor nerves which causes the sensation of a lump in the throat and is usually associated with enlargement of the lingual tonsil or a lingual varicosity *Spasmodic contraction of the pharynx and esophagus* which causes swallowing of air with subsequent eructation, is occasionally seen in chorea The *treatment* of these conditions is mental with correction of the causative factor

Sensory Neurosis.—Anesthesia of the pharyngeal mucosa occasionally complicates general nervous disorders It is most common in hysteric patients

Hyperesthesia frequently accompanies chronic inflammation of the pharynx

Paresthesia (sensations of suffocation tickling itching or of the presence of foreign bodies) is not uncommon in the neurotic or insane

T Laurance Saunders

DISEASES OF THE ESOPHAGUS

Life without use of the esophagus for introducing food into the stomach is difficult and the value of it questionable Many of the diseases which affect this long and relatively narrow tube interfere with the passage of food into the stomach with resulting malnutrition or even starvation Therefore although relatively infrequent these diseases are of importance The earlier the diagnosis is made the more satisfactory are the results of treatment hence careful consideration *should be given to the two cardinal symptoms*—pain or difficulty in swallowing

Diagnostic Procedure —The symptoms presented by the patient are of considerable aid in diagnosing diseases of the esophagus The description of the onset progress or persistence of the pain or difficulty in swallowing is helpful A complaint of gurgling noises on swallowing the regurgitation of food on change of position or during sleep accompanied sometimes with a strangling sensation or even strangling on swallowing is of significance Hoarseness may be present if the recurrent laryngeal nerve is involved With surprising accuracy a patient may identify the level of the lesion in the esophagus

So little of the esophagus is available for inspection and palpation that physical ex

amination reveals little except anemia, loss of weight, the presence of a tumor mass in the neck, and enlargement of the spleen which occurs in certain instances

X-ray examination in many instances will establish the diagnosis, but direct inspection through the esophagoscope should be carried out in all doubtful cases Material for a biopsy may be secured through the esophagoscope

Congenital Abnormalities—The esophagus may end in a *blind pouch* within the thorax The lower end of the esophagus in such instances may be connected to the upper by a fibrous cord or be entirely disconnected Either of these pouches may connect by fistula with the trachea or bronchus These infants usually succumb in a few days from starvation although surgeons are continually struggling with the problem If a fistula exists pneumonia usually develops if the infant is kept alive by some artificial method of feeding A fistula may exist between the trachea and a patent esophagus

Congenital cysts occur in the wall of the esophagus which may or may not cause symptoms of obstruction

Congenital dilatations or *narrowing* or even pouches of the esophagus occur which may or may not give symptoms The narrowing of the esophagus may need dilatation at once or may not produce symptoms until after some years

The *esophagus may be congenitally* so short that the stomach protrudes through the diaphragm to meet it This type of *diaphragmatic hernia of the stomach* may or may not produce symptoms

Diverticulum—Diverticula are of two types One the so called *pulsion* or *pressure diverticulum* is usually a real hernia of the mucous membrane through the muscular coats but in a few instances some muscle fibers are included in the sac These herniations occur where there is some defect in the muscle coats or where these have been weakened by disease or trauma and are the more frequent The other type is a so called *traction diverticulum* which is a distortion of the esophageal wall due to contraction of scar tissue in surrounding structures which have become adherent to the wall of the esophagus

Pulsion Diverticulum—SITE—The commonest site is at the junction of the pharynx and esophagus (sometimes called pharyngo esophageal diverticulum) at which point the muscle coats often fail to surround the tube completely Another site is at the natural narrowing of the esophagus caused by the left bronchus as it crosses in front Still another site is at the lower end of the esophagus just above the diaphragm Such diverticula are called supradiaphragmatic or epiphrenic The diverticulum at the upper end of the esophagus starts as a slight bulge which gradually increases in size until a sac has been formed large enough when filled to be seen and palpated As the sac increases in size it distorts the lumen of the esophagus so that obstruction to the passage of food into the stomach occurs These diverticula usually occur in people more than forty years of age

SYMPTOMS—The symptoms vary from the sensation of a particle of food stuck in the throat to difficulty or inability to swallow When the sac is large enough for food to collect in it and decompose, foulness of breath accompanied by dryness and irritation of the mucous membrane and excessive secretion of mucus result *Regurgitation* from the sac with leakage into the larynx especially at night produces strangling *Gurgling noises on swallowing due to* a mixture of fluid and air in the pouch may occur

DIAGNOSIS—*On physical* examination a tumor mass may be felt on one side of the esophagus and the size of the tumor will *diminish after regurgitation* The diagnosis is usually made by x ray examination Should esophagoscopic examination be indicated care must be taken not to rupture the sac due to the esophagoscope entering the sac rather than passing down the esophagus In the early stages while the sac is small dilatation of the esophagus *below the* diverticulum may retard appreciably its enlargement When the diverticulum produces enough symptoms it should be *removed by* surgical procedure Diverticula of this type in the midthoracic region and at the lower end of the esophagus *usually do* not interfere with swallowing but other symptoms are essentially the same For the midthoracic *diverticula dilatation* of the esophagus below the lesion is about the only procedure

available For the diverticulum at the lower end of the esophagus the surgeons suggest hitching the bottom of the sac upright in the mediastinum so that such food as passes into it will drain out

Traction diverticula rarely cause symptoms of importance but should food accumulate in the bulge, dilatation of the esophagus below with a dilator passed along a previously swallowed thread seems the most satisfactory procedure

Inflammation —Lesions may occur in the esophagus during the course of many infections such as the primary lesion of syphilis the eruption of smallpox the ulcers of typhoid fever or tuberculosis and the reactions associated with various acute infections including glanders actinomycosis and diphtheria Usually these lesions masked by the other symptoms of the disease are of little practical importance Acute inflammation of the esophagus may be produced by chemical irritants or pus forming organisms Thrush is an important cause in children These inflammatory agents may reach the esophagus from the mouth or by extension from adjoining structures A catarrhal condition of the esophagus may develop from less severely irritating substances acting over a long period

Symptoms —Acute inflammation causes pain along the course of the esophagus burning beneath the sternum often difficulty or pain in swallowing and a marked increase in the secretion of mucus in the pharynx and mouth Vomiting may occur usually with mucus and blood mixed with the vomitus Extreme thirst is a common symptom Should the inflammation become so severe that rupture of the esophagus occurs the patient will show marked prostration and localized symptoms dependent upon the structure into which the rupture has occurred The general constitutional symptoms and febrile reaction will depend on the severity of the process

Diagnosis —A history of swallowing some irritating substance is an important aid in diagnosis It is undesirable to use instruments blindly in an esophagus which is acutely inflamed for fear of rupture X ray studies are usually not indicated If the diagnosis is not satisfactory careful inspection with the esophagoscope may be tried

Treatment —The treatment of acute inflammation of the esophagus consists in removing the irritating causes if persistent and in giving the esophagus as complete a rest as possible Oil or cool drinks may be administered by mouth but food should be avoided for several days The fluid content of the body can be kept up by the introduction of fluid in other ways if the swallowing of cool drinks is too painful An ice bag brings comfort when applied to the esophagus above the thorax

As stenosis of the esophagus even up to complete stricture may result from acute inflammations it is important as soon as the acute phase has subsided to be prepared to dilate the esophagus should difficulty in swallowing develop These stenosing bands are often called webs If difficulty in swallowing should develop it usually begins between the fourth and sixth weeks A silk thread should be swallowed and dilatation carried out by instruments passed along the thread If appreciable stenosis has developed the dilatation will probably have to be carried out for two years at regular intervals to be followed for two or three years more by an occasional check up Should rupture of the esophagus occur during dilatation the results are not necessarily fatal and experience suggests that conservative treatment may be as satisfactory as immediate surgery

In neglected cases in which the obstruction is complete so that a silk thread cannot pass the stricture it may be necessary to resort to retrograde dilatation after gastrostomy A gradually stenosing esophagus should never be allowed to reach the stage where a silk thread will not pass into the stomach

Ulcers —In bedridden or uremic patients ulcers sometimes occur in the esophagus They may also result from external pressure upon the esophagus These ulcers are of little clinical importance because their symptoms are usually overshadowed by the symptoms of the accompanying disease Ulcers similar to peptic ulcers occur in the esophagus They may develop in misplaced bits of gastric mucosa present in the esophagus They may cause no symptoms of importance or they may produce pain or difficulty in swallowing and even regurgitation of food

The pain should not be confused with angina pectoris Such an ulcer may perforate or bleed and the hemorrhage be severe An ulcer in a diaphragmatic gastric hernia occasionally simulates an esophageal ulcer

Diagnosis without the use of the esophagoscope may be difficult when the x ray does not reveal the ulcer The *treatment* of such an ulcer is similar to that of a peptic ulcer in the stomach Local applications may be made through the esophagoscope but their value is doubtful

Spasm—Spasm of the esophagus with pain or difficulty in swallowing must be differentiated from hysterical manifestations such as *globus hystericus* and functional pain without difficulty in swallowing The spasm may be (1) diffuse or localized at the lower end of the esophagus (cardiospasm) or (2) at the upper end and be associated with enlargement of the spleen secondary anemia and glossitis (Plummer-Vinson syndrome)

Diffuse spasm of the esophagus or cardiospasm may be painless and present only the symptom of difficulty in swallowing In other cases the substernal pain may be severe enough to simulate angina pectoris There is some question as to whether an attack of angina pectoris can be brought on by spasm of the esophagus or whether spasm of the esophagus may be induced by an attack of angina pectoris The two however may be associated Spasm of the esophagus can be brought on by worry but not by muscular exertion and it is not relieved by nitroglycerin Such attacks may be associated with gallbladder disease The electrocardiogram will not be influenced by spasm of the esophagus X ray studies show obstruction to swallowing during the attack of spasm Difficulty in swallowing due to obstruction from something outside the esophagus such as an aneurysm must be ruled out The *treatment* for diffuse spasm of the esophagus consists in attention to the patient's general condition and the usual procedure for handling some one who is under a nervous strain or is emotionally unstable

Cardiospasm—Whether cardiospasm is due to abnormal spasm of the muscle fibers of the esophagus or failure of normal muscular contraction to relax is still a disputed question If it is persistent there may result tremendous dilatation of the esophagus and hypertrophy of the walls A case is reported in which a dilated and hypertrophied esophagus herniated into the abdominal cavity Cardiospasm should be differentiated from an organic lesion due to growth or stricture and usually this can be done by x ray study but occasionally an esophagoscopic examination is necessary Spasm may be superimposed upon an organic lesion Dilatation of the spastic area by an instrument passed along a previously swallowed silk thread is the usual method of treatment. This may be done without an anesthetic and often one dilatation will suffice Sometimes the cardiospasm will return after several years The patient s general condition and environment must be considered in regard to causes for reflex spasm

Plummer Vinson syndrome sometimes called hysterical dysphagia usually occurs in women more than forty years of age is more common among Scandinavians and inhabitants of the British Isles and is rare in Hebrews In addition to the evidence of an unstable nervous system there is hypochromic anemia enlargement of the spleen, and glossitis In these cases the obstruction is at the upper end of the esophagus and responds to dilatation with sounds Even the passage of a small sound without dilating the esophagus often results in complete cure. Recurrence may call for subsequent dilatation As the anemia and difficulty in swallowing disappear, the soreness in the mouth clears up and the spleen diminishes in size

Tumors—Both malignant and benign tumors of the esophagus occur Carcinoma is the most common type Sarcoma is rare Fibromas papillomas hemangiomas lipomas and accessory thyroid tumors have been observed in the esophagus and also diffuse fibromyomata involving practically the entire musculature of the tube Cysts may develop in the wall of the esophagus Benign tumors may become large enough to cause obstruction or they may become pedunculated and even protrude from the mouth.

Carcinoma—This tumor is more common in men than in women It is usually situated at one of the three natural narrowings of the esophagus (1) at its upper origin (2) at the point where the left bronchus crosses in

front of it, or (3) at the point where it passes through the diaphragm The last is the commonest site

SYMPTOMS —Increasing difficulty in swal lowing usually without pain is the most frequent initial symptom Pain in the epi gastrium is a fairly common initial symptom and loss of appetite or belching of gas and hiccoughs have been reported to be the first symptoms noted As the disea e progresses signs of starvation gradually develop The patient loses weight rapidly and constipa tion becomes prominent because of the small amount of food absorbed Thirst is very dis tressing if the obstruction is complete Hem orrhage may occur if ulceration is present The blood may appear in the vomitus or only as tarry stools

DIAGNOSIS —The x ray examination usu ally establishes the diagnosis but it should be confirmed by esophagoscopic examina tion and biopsy

TREATMENT.—Recent advances in at tempts to remove malignant growths from the esophagus and in the establishment of an artificial esophagus are encouraging enough to stimulate the clinician to diag nose these cases early and refer them to a surgeon If surgery is contraindicated the growth may be retarded by deep x ray ther apy If the obstruction is pronounced grad ual dilatation may give temporary benefit Feedings by rectum or through a gastros tomy opening are on the whole unsatisfac tory If thirst is present fluids should be in troduced by rectum under the skin or in the veins Opiates should be liberally employed as the disease progresses

Esophageal Varices —Dilatation of the veins at the lower end of the esophagus is common if there is any obstruction to the return of blood either through the inferior or superior vena cava or through the portal circulation because the veins of the esoph agus connect with all three and anastomose with each other The most common cause of dilatation of the veins of the esophagus is cirrhosis of the liver It may occur in dis ease of the spleen with a normal liver The dilated veins may not produce any symp- toms or they may rupture and cause a sud den unexpected hemorrhage Attempts to decide upon the cause of the unexpected hematemesis should not be made until the bleeding has entirely ceased and then blind instrumentation should be avoided If the x ray study fails to show the varices exam ination with esophagoscope is indicated

There is no specific *treatment* for dilated veins in the esophagus

Rupture —Rupture may occur in a nor mal or diseased esophagus Rupture in a normal esophagus has been reported as caused by persistent vomiting wounds of foreign bodies or from heavy lifting Forced swallowing in a diseased esophagus may cause rupture or the natural progress of the disease may produce it The rupture of a diseased esophagus may extend into the respiratory tract and produce a fistula Al though there has been some success in the surgical treatment of rupture it should be remembered that recovery has been reported without surgical interference The *diagnosis* is readily made by x ray study as it will show the barium passing outside the lumen of the esophagus

Foreign Bodies —A foreign body may lodge in the esophagus without producing symptoms or may produce symptoms of obstruction very rapidly In children in ad dition to the difficulty in swallowing there may be definite interference with respiration The x ray may demonstrate the foreign body either directly when it casts a direct shadow or by a defect in the barium shadow if the foreign body does not cast a shadow Occasionally the foreign body is revealed by the barium which adheres to it after the remainder of the barium has reached the stomach

A foreign body should be removed with the aid of the esophagoscope as soon as the diagnosis is made Attempts to push a for eign body into the stomach or the blind re- moval of a foreign body from the esophagus without preliminary inspection are both dan gerous procedures

DISEASES OF THE STOMACH

Anatomic Variations—The shape and position of the stomach depend upon the constitutional type of the individual, upon his adiposity, and upon the condition of his anterior abdominal musculature In the relatively short, thick sthenic person with tense abdominal wall the stomach lies high in the left upper abdomen and is "steer horn" in shape whereas in the long, lean thin individual, the greater curvature is likely to extend to the brim of the true pelvis in the shape of the letter "J" This condition is often called gastroptosis and a symptomatology erroneously ascribed to it The important consideration is not *where* the stomach is but *how* it functions and such stomachs do function satisfactorily The vague digestive symptoms and disturbances often seen in these patients are not due to the location or position of the stomach

WALTER L PALMER

CONGENITAL ANOMALIES

THE three important congenital anomalies of the stomach are hypertrophic stenosis of the pylorus diverticula and diaphragmatic herniation, including the so called "thoracic stomach" with a short esophagus

HYPERTROPHIC STENOSIS OF THE PYLORUS

Definition—Hypertrophic stenosis of the pylorus consists of an obstructive narrowing of the pylorus accompanied by and apparently due to hypertrophy of the pyloric muscle

In Infants—Hypertrophic stenosis is found most frequently in infants two or three weeks old although it may occur at any time between the ages of ten days and three or four months The condition is three or four times more common in males than in females It is generally attributed to congenital hypertrophy with or without spasm At operation or autopsy the pylorus is found to consist of an oval tumor of muscular tissue 2 to 3 cm long and 1 to 2 cm in width hard, at times almost cartilaginous in consistency, and with no histologic evidence of inflammation However patients are occasionally seen with the typical clinical syndrome in whom at operation no hypertrophy is found, the obstruction presumably being due therefore, to spasm

Symptoms and Diagnosis—The symptoms are projectile vomiting constipation or obstipation decreased urinary output and rapid loss of weight Bile is rarely present in the gastric content On physical examination the most characteristic feature is the demonstration of large peristaltic waves passing from left to right across a distended globular stomach which fills the upper abdomen after eating If the child is relaxed adequately a tumor resembling a small peanut or marble may be palpated frequently, deep in the abdomen at the outer border of the right rectus muscle a few centimeters below or immediately under the costal border The diagnosis of pyloric obstruction is confirmed by roentgenologic examination When the factor of *spasm* predominates a somewhat milder picture is seen The vomiting tends to be explosive rather than projectile the peristaltic waves are less marked and a tumor is not palpated The stools may be scanty and may be soft rather than hard in consistency These cases outnumber those of true hypertrophic stenosis of the pylorus by about 30 1 and usually respond well to medical treatment

Treatment—In both types, medical treatment should be tried first provided the condition of the infant warrants it Sodium phenobarbital ⅛ grain given immediately before each feeding is very effective more so than atropine but it may be combined with atropine 1/1000 grain Atropine alone in large doses is undesirable because it may produce distention of the bowel dryness of the nose and throat and cerebral stimulation The diet should consist preferably of breast milk or a prepared milk giving a fine curd Thick cereal feeding may be used The infant should be watched most carefully

If a definite and favorable response is not secured within a few days or if the symptoms grow worse with dehydration and fever operation should be performed at once When a tumor is palpable operation is, as a rule required and it may become necessary in cases in which a tumor is not palpable The surgical procedure known as the

Rammstedt operation and consisting of a longitudinal incision through the pyloric muscle down to the mucosa ranks among the most successful ones in the field of abdominal surgery and has a mortality rate in competent hands ranging from 2 to 6 per cent

In Adults —Hypertrophy of the pylorus is seen in adults with and without stenosis and with and without symptoms The congenital origin of the hypertrophy has been questioned It has been noted however that periodic attacks of nausea and vomiting are less frequent throughout childhood and later adult life in patients operated on in infancy for hypertrophic stenosis than in those treated medically Cases of periodic nausea and vomiting have been described beginning in childhood and continuing until old age in which the pylorus was found to be markedly hypertrophied by the development of massive muscular bundles apparently congenital in origin On the other hand in the adult pyloric hypertrophy is often associated with some acquired gastric diseases such as gastric ulcer or gastritis Some authors ascribe hypertrophy of the pylorus to extragastric lesions such as cholelithiasis and chronic appendicitis but there is little evidence to support such a view

Symptoms and Diagnosis —The primary symptom is vomiting with or without pain The pain is usually due to an associated lesion such as gastric ulcer for pyloric obstruction *per se* does not produce pain The diagnosis of hypertrophic stenosis in the adult cannot or should not be made on clinical evidence alone Roentgenologically it may be evident from dilatation of the stomach the abnormal width of the pylorus and the crescentic indentation of the base of the bulb although in some normal individuals the pylorus is quite wide and a crescentic indentation may be made out in the base of the bulb An important and difficult task is the differentiation of benign and malignant hypertrophy of the pylorus the so called *carcinoma fibrosum* which usually begins in the pyloric end of the antrum The history in such cases is usually of short duration whereas in true hypertrophic stenosis it extends over many years Roentgenologic evidence of neoplasm may be found in an infiltration of the antrum and an absence of the crescentic indentation of the bulb In cases of pyloric hypertrophy associated with gastric ulcer or of gastric ulcer associated with pyloric hypertrophy the ulcer may produce little or no pain and be unsuspected until demonstrated roentgenologically or gastroscopically

Treatment —Treatment depends upon the severity of the symptoms and upon the associated conditions present If the stenosis is not marked no treatment may be in order If gastric ulcer is present the usual ulcer management may be followed unless the pyloric obstruction interferes If any reasonable doubt exists as to the nature of the pyloric lesion operation should be seriously considered Exact differentiation is usually as difficult at the operating table as it is preoperatively and hence as a rule in such questionable cases if operation is undertaken subtotal gastrectomy should be performed In true hypertrophic stenosis pyloroplasty or simple gastro-enterostomy may be sufficient Atropine is of no value in the differentiation of the various types of pyloric hypertrophy or in their therapy

WALTER L PALMER

DIVERTICULA

Definition —A diverticulum is a pouch opening out from a tubular organ True diverticula contain all of the coats of the normal stomach and are either congenital or secondary to pulsion and traction false diverticula lack the muscular coats and are attributed to weakening of the gastric wall from local disease as in gastric ulcer

Incidence and Location —True diverticula of the stomach are rather uncommon false diverticula are quite rare Both types are encountered as a rule accidentally in the course of a routine x ray examination or at autopsy They are seen most frequently roentgenologically in the region of the cardia but any part of the stomach may be involved Duodenal diverticula are more common than gastric Congenital diverticula of the duodenum occur usually in the second and third portions whereas acquired diverticula develop almost exclusively in the first portion Practically all diverticula of the

duodenal bulb are secondary to duodenal ulcer

Symptoms—Gastric and duodenal diverticula rarely cause distress although occasional cases have been described in which a marked inflammation was found about the duodenal diverticulum and relief of epigastric distress obtained by the removal or *invagination of the diverticulum* The belching discomfort, or pain is usually to be attributed to the acompanying disease or to a functional disturbance independent of the diverticulum

Treatment—Direct treatment of the diverticulum is rarely indicated Concomitant diseases such as ulcer or carcinoma or concomitant functional disturbances should be treated appropriately Relief from the distress is usually obtained without directing attention to the diverticulum In rare cases surgical treatment with excision or invagination of the diverticulum may be required

WALTER L PALMER

DIAPHRAGMATIC HERNIA

Diaphragmatic hernia is discussed in the section on Diseases of the Diaphragm (p 886)

FOREIGN BODIES IN THE STOMACH

Description—The foreign bodies most frequently swallowed are those taken accidentally by children, such as pennies and marbles, which in time pass through the stomach and intestine without harm Sharp-pointed articles, such as needles pins, and especially open safety pins are likely to penetrate the wall of the intestine and lead to peritonitis or abscess formation In the insane, the stomach may be found to contain a most varied assortment of nails spoons forks knives and other objects which may remain for years without causing symptoms *Bezoars* are conglomerations of swallowed foreign material such as hair (trichobezoars) hair and vegetable fiber (trichophytobezoars) or vegetable fiber alone (phytobezoar), usually due to persimmons *Hair balls* are the most frequent and are found in women addicted to the habit of chewing the ends of their hair *Gastroliths* have been reported from the long continued use of calcium or magnesium powders Spontaneous cholecystogastric fistula formation may lead to the extrusion of *gall stones* into the stomach

Symptoms—Foreign bodies in the stomach rarely cause symptoms unless there is an associated ulcer or gastritis

Treatment—Treatment is indicated only when definite distress is present or when the foreign body constitutes a real menace as in the case of a needle or an open safety pin The procedure indicated is usually surgical removal by means of laparotomy, for this is on the whole less dangerous simpler and more effective than open tube gastroscopy

DISTURBANCES OF GASTRIC FUNCTION

SENSORY DISTURBANCES

Hunger and Appetite—Hunger and appetite were interpreted by Beaumont and subsequent workers as sensations differing only in degree but Cannon and later Carlson, very carefully differentiated the pleasant sensation of appetite related to previous sensations of the smell and taste of food from the disagreeable and painful sensation of hunger the essential factor of which the epigastric hunger pang was shown to be produced by contractions of the empty stomach The average individual in fasting does not distinguish sharply between hunger and appetite for the accentuation of the appetite is interpreted merely as a portion of the *total complex of hunger*, which may be divided into the following components

(*A*) Sensory

1 Pleasant olfactory and gustatory sensations with their associated pleasant memories of the taste and smell of food constituting appetite

2 Painful 'hunger pangs resulting from contractions of the empty stomach or intestines

3 An indefinite unpleasant generalized steady and continuous sensation interpreted as hunger and vaguely referred to the abdomen
4 Accessory phenomena such as lassitude weakness drowsiness faintness irritability restlessness and headache

(B) Associative or Imaginative The mind associates these various sensations with indefinite concepts of food or with definite images of specific foods

The phenomenon of hunger is thus seen to be a complicated sensory and associative process consisting of an accentuation of the pleasant sensation of appetite and the various unpleasant sensations of hunger including the painful contractions of the empty stomach and all associated with definite or indefinite concepts or imageries of food

Excessive appetite and *hunger* occur in various conditions such as in convalescence from an acute infectious disease like typhoid fever The digestive tract is then able to digest and absorb unusual amounts of food in order to restore rapidly the weight lost earlier A similar condition may obtain in thyrotoxicosis in which the requirement of food is maintained at a high level because of the excessive metabolism In diabetes mellitus the glucose in the blood is not available to the tissues and hunger and polyphagia result In peptic ulcer the distress is often interpreted as hunger because the patient fails to differentiate it from a hunger pang or because it occurs when the stomach is thought to be empty and is relieved by food taking The epigastric pang of hunger and the pain of peptic ulcer arise in the same organ and have in part but in small part only the same mechanism

Bulimia a term applied to an inordinate appetite and food intake is a purely psychologic phenomenon Continued excessive hunger and its resultant excessive ingestion of food lead eventually to obesity except in diabetes mellitus or thyrotoxicosis

Loss of appetite and of *hunger* is a variable but common symptom in disease of all kinds When it appears suddenly in individuals known to have been in good health it is a highly important symptom and warrants a most thorough search for the cause It is an early and prominent symptom in many cases of gastric or pancreatic neoplasm Therapeutically the primary indication is that of the underlying disease Liver and liver extract are curative in the anorexia of pernicious anemia In other deficiency states such as beriberi and pellagra the administration of brewers yeast or of thiamine chloride or of nicotinic acid results rather dramatically in improved appetite and increased food consumption Multiple vitamin deficiencies are probably more frequent than has been recognized generally and are relieved by proper therapy but nevertheless vitamins cannot be relied upon as a universal cure for loss of the desire for food Stimulation of the appetite itself is largely a psychologic problem Good food served attractively and with a cheerful smile is essential Stomachics are of suggestive value only Alcoholic beverages may be helpful if given with adequate suggestion but care must be exercised lest a neurotic individual take advantage of the opportunity afforded to become a chronic alcoholic Insulin seems to increase appetite hunger and food consumption in certain individuals but it too is of greatest value if given with strong suggestion

Anorexia Nervosa —*Definition* —Anorexia nervosa first clearly described by Sir William Gull in 1868 is a syndrome consisting of emaciation scaphoid appearance of the abdomen and amenorrhea It occurs chiefly in young girls but except for the amenorrhea the essential features of the syndrome are seen in both sexes and in almost all age groups Gull considered the condition to be due to a psychic loss of appetite resulting from a morbid mental state and so named it anorexia nervosa'

Symptoms and Diagnosis —Loss of appetite is the outstanding feature of the disorder and yet one about which the patient rarely complains The emaciation may be extreme progressing even to the point of nutritional edema The tissue of the breast is said to be preserved but it is often very scant A striking characteristic noted by Gull and subsequent observers is the wilfulness and remarkable energy of these patients which is in strange contrast to their prematurely senile or cachectic appearance

The basal metabolic rate may be markedly lowered The glucose tolerance curve is, as a rule, low or indeed almost a straight line, indicating presumably a delayed intestinal absorption, for the curve is normal when the glucose is given intravenously After recovery from the inanition the curve becomes normal The axillary and pubic hair are usually well preserved may become sparse but are almost never absent a point perhaps of value in differentiating the condition from Simmonds' disease in which such loss of hair is considered rather characteristic Careful inquiry will usually disclose *some precipitating nervous or emotional* cause The patient may have considered herself overweight, started to reduce and continued the procedure or she may have taken this means to express a parental conflict or her disappointment in love Skilful management usually leads to recovery but death *may ensue Considered from the psychiatric* point of view the mental patterns of anorexia nervosa are not uniform Most of them are psychoneuroses or depressions of various kinds, but in some cases, the picture approaches the true psychosis

Treatment — Superficial psychotherapy with encouragement and friendly interest perhaps conveyed with tonics and stomachics may suffice in the milder cases Often, however a temporary or even a permanent change of environment is essential The mode of living or the "life situation' may need readjustment Formal psychiatric care including psycho analysis may be indicated Success is usually achieved with some one of these measures but occasionally *all of them fail Thyroid extract* is not indicated for the low metabolic rate for this returns to a fairly normal level once satisfactory nutrition and consumption of food are achieved The low metabolism is a manifestation of *starvation rather than* primary hypothyroidism

Simmonds' Disease —*Definition* —Simmonds disease described by Simmonds in 1914 is a similar syndrome attributed to destruction of the anterior *lobe of the pituitary* gland

Symptoms and Diagnosis —It is difficult if not impossible, to distinguish clinically the syndrome of Simmonds' disease from that of anorexia nervosa Typically *the patient with* Simmonds' disease is a parous woman past forty years of age The symptoms are emaciation *premature aging* gonadal atrophy amenorrhea, loss of libido dental caries and loss of teeth microsplanchnia marked depression of the metabolic rate loss of hair from the axillae, pubes and scalp, and various abnormal mental reactions The apathy is often contrasted with the remarkable energy seen in anorexia nervosa Symptoms such as these are all known to result from continued loss of appetite and chronic inanition The question arises whether Simmonds' disease is an advanced and chronic form *of anorexia* nervosa with secondary changes in the pituitary gland or whether anorexia nervosa is to be attributed to a functional disturbance of the pituitary, or whether the two conditions are independent of each other Cases of the Simmonds syndrome have been de*scribed with and without* definite disease of the pituitary at autopsy Anterior pituitary disease occurs without the Simmonds syndrome Experimentally emaciation and cachexia may follow extirpation of the pituitary or be produced *by chronic* inanition in which case glandular changes are present

Treatment —The therapeutic value of specific or nonspecific glandular therapy has not been proved although in many instances improvement has followed the *use of such* measures and has therefore been ascribed to them Regardless of the relationship ultimately found to exist between Simmonds disease and anorexia nervosa the therapeutic indications are the same in *both* and are symptomatic and psychotherapeutic in *nature In extreme* cases feeding through a nasal catheter or the parenteral administration of fluid may be necessary for a few days or weeks

Nervous Vomiting —Nervous vomiting *is strictly speaking* neither a sensory nor a motor disturbance of the stomach but it may be briefly considered here because it is a manifestation of a basic psychiatric problem similar to anorexia nervosa It is in *some respects more* dramatic but less subtle than anorexia and more typically hysterical in nature although the patient usually does not appear to be hysterical The *most* characteristic feature is the continued effortless *vomiting of meals* usually immediately after

eating with no loss of weight The patient complains bitterly but looks well Gastric and esophageal disease particularly cardio spasm should be excluded The therapy is a psychiatric problem Sedatives are valuable Fluids should be administered parenterally for a few days until the acute phase has passed The chronic forms of nervous vomiting may be very resistant to treatment

Migraine —Migraine is not a disease or a primary disorder of the stomach The nausea and vomiting are primarily psychogenic or at least central in origin So-called abdominal migraine is abdominal only in that abdominal symptoms particularly nausea and vomiting are present and dominate the clinical picture The headache is the essential although often not the outstanding feature of the syndrome and gives the clue to the diagnosis

WALTER L PALMER

MOTOR DISTURBANCES

Gastric atony is not a clinical entity The large sagging stomachs of gastroptosis may empty slowly but they are not abnormal and do not give rise to symptoms In pyloric obstruction the stomach is dilated but not atonic

Hyperperistalsis and hypertonicity of the stomach are likewise not disease entities or the basis for symptoms They are often found in tense nervous individuals in patients with duodenal ulcer in the presence of complete achlorhydria and occasionally in gastric carcinoma In diabetes mellitus the contractions of the empty stomach may be increased and lead to inordinate hunger

Spasm of the entire stomach or of a segment of the stomach has been described in tabes dorsalis in other lesions of the central nervous system and also in the presence of extragastric abdominal conditions such as cholelithiasis or pancreatic disease The relationship of such spasm to abdominal pain is questionable for the pain of tabetic gastric crises seems not to arise in the stomach itself and segmental gastrospasm has been observed without pain On the other hand painful gastric spasm has been noted in the normal stomach Localized muscular spasm is not infrequently seen with gastric lesions as in hour glass contracture associated with benign ulcer, the contracture disappearing when the ulcer heals Painless spasm of the pylorus as evidenced by rather persistent closure occurs frequently with intrapyloric peptic ulcer and also with gastric and duodenal lesions adjacent to the pylorus Gastric ulcers several centimeters proximal to the pylorus on the lesser curvature are occasionally associated with a disturbance in the opening of the sphincter, presumably a reflex pylorospasm Contractions of the pylorus and of the stomach are on the whole independent of the sensation of pain but may be painful if sufficiently intense or if they occur in the region of an ulcer

Acute Dilatation of the Stomach —*Definition* —Acute dilatation of the stomach or acute gastromesenteric ileus is as the name implies a condition in which the stomach is extremely dilated flabby inactive and contains 1500 to 4000 cc of thin slightly colored gastric and intestinal liquid content The condition occurs chiefly as a postoperative or postpartum complication and is due to compression of the third portion of the duodenum between the spine and aorta posteriorly and the mesenteric root anteriorly Gastric dilatation is in part secondary to the obstruction and in part induced by the depression in gastric tonus resulting from the general anesthesia It is quite possible that the depression in gastric tonus precedes rather than follows the obstruction Another important factor may be the maintenance of the dorsal position for relief occasionally follows a change in position

Symptoms —The symptoms are variable and apparently result from distention of the stomach the loss of water and electrolytes and toxemia of indefinite origin The onset often is insidious the symptoms not marked and the severity of the condition not appreciated Pain is often slight or absent The more important symptoms are listlessness apathy lack of appetite epigastric fulness regurgitation nausea and vomiting The vomitus is usually dark brown green or black in color as a rule very foul smelling and copious consisting of large quantities of gastric biliary and pancreatic secretions The abdomen is soft distended without visible peristaltic waves and gives a succussion splash The urine is scant As the con

dition progresses the signs of shock or collapse appear, a cold clammy skin, anxious facies, rapid pulse, low blood pressure, shallow, quick respirations and delirium, followed by coma and death

Treatment —Treatment consists of gastric lavage, the administration of large amounts of fluid parenterally, and frequent changes in position In the modern hospital, the routine postoperative use of the Wangensteen continuous *suction apparatus* has proved most effective In some cases the suction must be continued for several days but if the parenteral replacement of fluids is adequate, usually 2 to 4 liters per twenty four hours recovery occurs

WALTER I PALMER

SECRETORY DISTURBANCES

Normal and Abnormal Variations in Gastric Secretion —Pathologic alterations in gastric secretion apparently occur exclusively in the direction of depression in total volume or in concentration or both The normal stomach secretes gastric juice *as acid as that in disease and as far as* is known in as large an amount although there is some evidence that in many cases of ulcer particularly those associated with stenosis the night secretion of acid gastric juice is greater than that usually seen in normal individuals Variations in gastric secretion are not directly correlated with gross or microscopic changes in the gastric mucosa Normal individuals with essentially normal mucosae, gastroscopically exhibit a wide variety of responses to histamine ranging from complete achlorhydria with a *p*H value of 8 7 to a highly acid juice with a hydrogen ion concentration of 0 1 normal (*p*H 1 0) These differing secretory rates are not to be correlated definitely with specific symptoms or diseases except for the fact that chronic peptic ulcer does not occur in the continued absence of acid gastric juice nor does pernicious anemia or combined column degeneration of the spinal cord occur in its presence

Achlorhydria —*Occurrence* —The complete absence of all gastric juice *achylia gastrica* is rarely seen for some secretion containing *ferments* in small amounts is almost always present. The more exact terms *achlorhydria* and *anacidity* are preferable Complete achlorhydria as shown by the absence of acid in the gastric secretion even after the subcutaneous injection of histamine hydrochloride, so called histamine proved achlorhydria occurs in approximately 10 per cent of all individuals, in about 60 per cent of patients with gastric carcinoma in about 85 per cent of cases of gastric lues in nearly *all cases of adenomatous polyps or gastric* polyposis, and in all patients with pernicious anemia or combined cord degeneration

Etiology —The anacidity is usually ascribed to atrophic gastritis because such mucosal changes are found histologically in pernicious anemia It has been observed however that in many cases of anacidity with gastric carcinoma the mucosa is not atrophic histologically and no pathologic changes are evident to account for the achlorhydria Similarly in many cases of histamine proved anacidity in apparently normal individuals the mucosa as seen gastroscopically is essentially normal or shows evidence of relatively slight or patchy inflammation On the other hand extensive *atrophy of the gastric mucosa* undoubtedly leads to a depression or suppression of gastric secretion although surprising degrees of atrophy may be seen gastroscopically in stomachs found to secrete acid gastric juic

Symptoms —Achlorhydria *per se* is not important clinically It does not produce gastric symptoms From the standpoint of digestion it is also not particularly important for intestinal digestion almost *completely* compensates for the absence of gastric digestion The stomach empties somewhat more rapidly in achlorhydria than it does *when acid is present*, but this process is not affected by the oral administration of acid The term *gastrogenous diarrhea* referring to diarrhea with achlorhydria is not appropriate for there is no satisfactory proof that the diarrhea is related *to the achlorhydria* The functional diarrheas seen in patients with achlorhydria do not differ in their symptomatology or in their response *to dietary management* from those seen in individuals with acid gastric secretion

Treatment —The time-honored therapy is dilute hydrochloric acid given in doses of 1 to 4 cc in a half to a whole glass of water

before each meal The results are often strik ing but similar results may be obtained without the use of acid suggesting that the real role of the acid is that of a psycho therapeutic agent The amount of acid ac tually given is too small to alter materially the hydrogen ion concentration of the gas tric or intestinal content

NONSPECIFIC INFLAMMATION OF THE STOMACH

Definition—The term gastritis is usu ally applied only to acute or chronic non specific inflammations of the gastric mucous membrane although strictly speaking specific *lesions such as syphilis tuberculosis* and actinomycosis should be included

Morbid Anatomy—Acute and chronic inflammation is the most frequent pathologic process of the stomach Interstitial cellular infiltrations with collections of lymphocytes are almost invariably found in the wall of the stomach at autopsy More marked al terations such as hemorrhage in the super ficial layers of the mucosa erosion of the papillae and infiltration of the submucosa muscularis and serosa with lymphocytes plasma cells and polymorphonuclear leuko cytes are frequently observed Chronicity is evidenced by fibrous tissue proliferation in the gastric wall atrophy of the mucosa dis tortion or disappearance of the glandular structure and transformation of the normal glandular epithelium into the intestinal type with numerous goblet cells

WALTER L PALMER

ACUTE GASTRITIS

Description—Acute gastritis was orig inally and beautifully described in 1833 by William Beaumont who studied the mu cosa of the stomach of his servant Alexis St Martin through the fistula produced by a gunshot wound There are sometimes found on the internal coat of the stomach eruptions *or deep red pimples* not numer ous but distributed here and there upon the villous membrane rising above the sur face of the mucous coat. These are at first sharp pointed and red but frequently be come filled with white purulent matter At other times irregular circumscribed red patches varying in size or extent, from half an inch to an inch and a half in circum ference are found on the internal coat These appear to be the effect of congestion in the minute blood vessels of the stomach There are also seen at times small aphthous crusts in connection with these red patches Abrasions of the lining membrane like the rolling up of the mucous coat into small shreds or strings leaving the papillae bare for an indefinite space is not an uncommon appearance These changes came often lasted one day or more and disappeared

Etiology—With regard to etiology Beau mont states that After excessive eating or *drinking chymification is retarded* and although the appetite be not always im paired at first the fluids becomes acrid and sharp excoriating the edges of the aperture and almost invariably produce aphthous patches and the other indications of a dis eased state of the internal membrane

Symptoms—Beaumont s word again is authoritative These morbid changes and conditions are however seldom indicated

by any ordinary symptoms or particular sensations described or complained of, unless when in considerable excess, or when there have been corresponding symptoms of a general affection of the system They could not in fact, in most cases, have been anticipated from any external symptoms, and their existence was only ascertained by actual ocular demonstration

'It is interesting to observe to what extent the stomach, perhaps the most important organ of the animal system, may become diseased without manifesting any external symptoms of such disease or any evident signs of functional aberration Vitiated secretions may also take place, and continue for some time, without affecting the health in any *sensible* degree' In the century since Beaumont, these observations on the signs and symptoms of acute gastritis have been repeatedly confirmed Perhaps greater emphasis should be given to the incidence of such changes as seen pathologically in the course of all types of acute infectious disease However in spite of its frequency acute gastritis is probably of little clinical significance except as it may relate to chronic gastritis and its sequelae

Treatment—The treatment as implied by Beaumont, is that of abstinence from dietary indiscretions or perhaps indeed temporarily from all food Healing of the lesions and a return to a normal mucosa invariably occurs within a few days

WALTER L PALMER

ALCOHOLIC GASTRITIS

So called alcoholic gastritis is frequently diagnosed clinically on the basis of the clinical syndrome of nausea and vomiting after the ingestion of alcoholic beverages After a drinking bout the vomiting may be so persistent that the patient is unable to retain food or drink of any kind for several days The vomitus usually contains bile considerable amounts of mucus occasional flecks of blood and not infrequently streaks or even larger amounts of blood Hirsch in a histologic study of the stomachs of thirteen alcoholic addicts nine of whom had died of delirium tremens found no evidence of an acute or chronic inflammation Schindler and Gray, in a gastroscopic study of 100 men who had consumed an average of 2⅘ pints of alcohol daily for more than twenty years found the stomach to be normal in fifty five. The morning nausea is very difficult to explain It occurs as frequently when the stomach is normal as when it is diseased The symptoms are more likely to appear if the first swallow taken is water than if it is alcohol After two or three drinks of alcohol the nausea and vomiting usually disappear and do not recur until the following morning

WALTER L PALMER

CHRONIC GASTRITIS

Pathologic features of chronic gastritis cannot be directly or precisely correlated with clinical syndromes Indeed the diagnosis of chronic gastritis should be made only on the basis of anatomic evidence obtained at autopsy or laparotomy, or by gastroscopy The correlation between the pathologic and gastroscopic methods of study is fairly good Gastroscopically Schindler recognizes superficial atrophic and hypertrophic types of chronic gastritis

Superficial Gastritis—This condition is characterized gastroscopically by (1) reddening of the mucous membrane, (2) edema and (3) exudation The mucosa is friable small purpuric spots are common and small erosions are not infrequent The terms hemorrhagic erosive or ulcerative may be used in addition to superficial to describe the various features present The symptomatology if any of chronic superficial gastritis is still debatable for no one has succeeded in establishing a *definite gastritic* syndrome The condition is not infrequently seen gastroscopically in patients without gastric symptoms at the time of the examination it is rarely to be interpreted as the cause of distress The etiology is unknown and no treatment is indicated although numerous therapeutic programs have been advocated

Atrophic Gastritis—*Description*—The characteristic gastroscopic features are (1) the gray or greenish gray color due to the thinning of the mucosa in sharp contrast to the orange-red color of the normal stomach and (2) the presence of branching blood vessels seen through the thin mucosa Hemor

rhage into the mucosa is more frequent in this type of gastritis than in the others while erosions are less frequent The atrophy is usually rather localized and patchy in distribution but the entire mucosa may be involved

Relation to Other Diseases —In pernicious anemia during the phase of relapse the entire mucosa is invariably atrophic but marked improvement occurs following treatment with liver extract The propriety of ascribing the atrophy of the gastric mucosa in this disease to gastritis is still debatable In certain cases of iron deficiency anemia the gastric mucosa is also atrophic and improves markedly in appearance following suitable therapy Schindler considers that atrophic gastritis is usually the end result of a continued superficial gastritis There is a great deal of evidence that atrophic gastritis is the precursor or common etiologic background of pernicious anemia gastric polyposis and gastric carcinoma (see Fig 62) Certainly an atrophic gastric mucosa is present in all cases of pernicious anemia and is frequently found in neoplastic changes of the mucosa Konjetzny has presented histologic evidence of the complete transition from atrophic gastritis to benign and malignant epithelial neoplasia Considered in this light atrophic gastritis would appear to be a very important disease

Symptoms —The symptoms if any are indefinite although anorexia heartburn and various dyspepsias have been ascribed to it

Treatment —There is no acceptable evidence that treatment is of value except in those cases associated with pernicious or iron-deficiency anemia Hydrochloric acid may be given but it is of psychotherapeutic value only The possibility of carcinomatous metaplasia may be used as an argument for therapy in atrophic gastritis but this is scarcely permissible until more is known with regard to the actual occurrence and incidence of such neoplasia and also the real value of any proposed therapeutic procedure

Hypertrophic Gastritis —*Description* — This condition is characterized gastroscopically by a velvety slightly swollen dull loose spongelike appearance of the mucosa usually with the formation of granular nodules and larger nodes as may be indicated by the commonly used adjectives granular 'nodular verrucose' and hemorrhagic' At times the polypoid nodes may be difficult to differentiate from true polyps and neoplastic infiltrations Erosions and small ulcerations are frequent and usually multiple The cause of hypertrophic gastritis is unknown

Symptoms —There is evidence both clinical and histologic that the erosive and ulcerative forms of gastritis particularly in the hypertrophic type may cause symptoms consisting not only of epigastric distress identical with that seen in peptic ulcer but also massive gastric hemorrhage

Treatment —In such cases the distress disappears following the administration of a bland diet or the institution of a therapeutic program such as that used in peptic ulcer a more or less conventional Sippy program but the gastroscopic evidence of hypertrophic gastritis usually persists Symptomatic relief, however is all that is required for it is not necessary to insist on disappearance of the lesion as is the case in peptic ulcer Gastric lavage with silver nitrate or other medicaments is not indicated Following intensive radiation therapy directed at the stomach hypertrophic gastritis disappears and rarely recurs but the condition is almost never severe enough in itself to justify such treatment

Gastritis of the Postoperative Stomach —This is not a separate type of gastritis but it deserves special mention because of its severity and because it consists of a combination of the superficial and hypertrophic forms with marked erosive and hemorrhagic features In some cases the indefinite symptoms of epigastric distress and discomfort seem definitely attributable to the severe gastritis present There is no specific therapy and hence the treatment must be symptomatic When definite erosions and ulcers are present the therapeutic problem is that of recurrent ulcer

Gastritis Simulating Carcinoma —This also is not a separate type of gastritis but it deserves special mention These rather rare cases present clinical roentgenologic gastroscopic and indeed pathologic difficulties The inflammation involves chiefly the antrum and is accompanied by polypoid or pseudopolypoid changes in the mucosa which may be interpreted as precarcinomatous

proliferations, as "gastritis not yet carcinomatous" The polypoid infiltrative process is very difficult to differentiate from infiltrative neoplasm and is best treated by subtotal gastrectomy

SPECIFIC INFLAMMATION OF THE STOMACH

CORROSIVE GASTRITIS

THIS type of inflammation follows the ingestion of corrosives, particularly acids taken accidentally or with suicidal intent Perforation of the stomach and death may ensue or spontaneous recovery may occur Pyloric stenosis may result either from the acute inflammation or from the connective tissue proliferation and require surgical relief

WALTER L PALMER

PHLEGMONOUS GASTRITIS

This is an acute, infectious usually pyogenic inflammation of the stomach involving chiefly the submucosa It occurs as a rare complication of septicemia or other infectious processes as a rare surgical complication following operations on the stomach or other intra abdominal organs as a complication of peptic ulcer or more frequently of gastric carcinoma Focal abscesses of the mucosa and submucosa are not infrequently seen in the gastritis associated with gastric carcinoma but true phlegmonous gastritis is rare The symptoms consist of the sudden appearance of acute epigastric pain and fever often preceded by a chill with vomiting prostration a rapid weak pulse and rapid exitus The diagnosis is very rarely made antemortem In the pre sulfonamide era there was no specific or empiric treatment Now the sulfonamide should be used, although their value in this disease is not yet established

WALTER L PALMER

SCIRRHOUS OR SCLEROSING GASTRITIS

This lesion commonly called *leather bottle stomach* or *linitis plastica* is very rare The stomach is small contracted and rigid, due to a diffuse fibrous thickening of the submucosa It is customary to speak of two types benign and malignant The nature of the *benign* type is debatable Gastric syphilis may produce a diffuse fibrosis of the stomach Scirrhous *carcinoma* of the stomach is rather common and it is well recognized that in some cases of this type the tumor cells may be extremely difficult to demonstrate histologically The course may be very chronic It is quite probable that all cases of *linitis plastica* are luetic or neoplastic in origin and that a nonspecific benign type does not exist but conclusive proof is lacking The outstanding symptoms are moderate epigastric distress inability to eat more than a small meal, regurgitation belching and loss of weight (see Fig 65)

WALTER L PALMER

GASTRIC LUES

Incidence —Syphilis of the stomach is relatively rare but it occurs in all age groups and in both sexes although it is more frequent in males

Morbid Anatomy —As in all tertiary lues the characteristic pathologic lesion is the gumma Four different types are seen (1) The solitary ulcerated gumma (2) multiple ulcerated gummata forming a nodular serpiginous syphilid (3) diffuse nodular non ulcerated infiltration (4) chronic fibrosis The first type simulates benign gastric ulcer in appearance whereas the other three simulate carcinoma Histologically, perivascular round cell infiltration gummata obliterating endarteritis and phlebitis and with the appropriate technic *Treponema pallidum* may be demonstrated

Symptoms —The symptoms are variable

but epigastric pain or discomfort is the out standing feature The distress may simulate peptic ulcer but more often it suggests car cinoma in that it comes on immediately after eating and is accompanied by a marked loss of weight A mass may rarely be pal pable but massive hemorrhage and acute perforation almost never ocur Achlorhydria is present in about 85 per cent of the cases and gastric retention is noted in about a fourth

Diagnosis —The positive diagnosis of gastric syphilis is difficult The Wassermann test is almost always positive in the blood or spinal fluid or both Occult blood is not found in the stools Roentgenologically the lesion very rarely consists of a penetrating niche but usually suggests an infiltrative tumor The most frequent location is pre pyloric the defect concentric symmetrical and relatively smooth In some cases the middle of the stomach is involved in a dumbbell shaped deformity, the central con striction being as a rule long and tubular but occasionally forming a narrow hour glass In a small percentage of the cases the stomach is diffusely involved

Very few cases have been studied gastro scopically Schindler considers the demon stration of a brownish yellow very shallow large ulcer in a thickened gastritic area to be suggestive of syphilis

The problem of differential diagnosis arises almost exclusively in patients with a history or definite clinical evidence of lues including a positive serology Benign peptic ulcer and carcinoma are encountered in such patients much more frequently than is luetic involvement of the stomach

Treatment —A syphilitic gastric lesion should respond rapidly to antiluetic therapy If it does not and if occult blood is pres ent in the stool carcinoma is almost in variably present The diet is relatively un important The pyloric stenosis may be suf ficient to warrant gastro enterostomy

Walter L Palmer

TUBERCULOSIS OF THE STOMACH

This process is usually demonstrated at autopsy as an accidental finding in patients dying from pulmonary tuberculosis Clagett and Walters however found reports in the literature of 368 cases of clinically significant tuberculous gastric lesions of four pathologic types (1) the ulcerating type (2) the hypertrophic infiltrating type (3) acute miliary dissemination (4) extragastric lesions involving the stomach In at least 80 per cent of the cases the ulcerating type is the one found For some strange and un known reason about 10 per cent of the tu berculous lesions are associated with gastric carcinoma Clinically it is not possible to differentiate tuberculosis of the stomach from benign ulcer carcinoma or syphilis As yet the gastroscopic differentiation of tuberculous ulcers has not been made due perhaps to their rarity A positive diagnosis is established only by the demonstration of tubercle bacilli in the lesions Treatment is surgical resection of the involved portion being the operation of choice

Walter L Palmer

LYMPHOGRANULOMATOSIS

Hodgkin s disease may begin in the lymph oid tissue of the stomach and simulate car cinoma clinically roentgenologically and gastroscopically The diagnosis is usually made by the histologic examination of the resected specimen or of an excised lymph node

Walter L Palmer

RARE INFECTIONS OF THE STOMACH

Actinomycosis anthrax fungus infections nonspecific granulomatous ulcers diphther itic lesions and *agranulocytic ulcers* of the stomach are rare lesions seen at autopsy al most exclusively and hence they scarcely deserve clinical mention

GASTRIC NEOPLASMS

MESENCHYMAL TUMORS

Definition —Pathologically, gastric neoplasms may be divided into those of mesenchymal and those of epithelial origin but their clinical differentiation is difficult The mesenchymal tumors consist of fibromas myomas fibromyomas leiomyomas, myofibromas, hemangiomas, lipomas, angiomas dermoid cysts and the malignant sarcomas including the lymphoblastomas

Symptoms —Symptoms appear only when the tumor ulcerates bleeds obstructs the outlet of the stomach or becomes so large as to become noticeable to the patient as an abdominal mass The clinical picture is not characteristic There may be no symptoms Epigastric distress if present is usually not severe it may be induced by the taking of food relieved by food, or bear no relationship to food taking The symptoms and signs of anemia are often present

Diagnosis —Mesenchymal neoplasms occur in all age groups, but the finding of a gastric tumor in a patient in the first or second decade of life would be suggestive The roentgenologic demonstration of a circumscribed, apparently intramural nonulcerated mass would conform with the diagnosis of a relatively benign mesenchymal tumor such as a myoma or fibroma Gastroscopically such a diagnosis is indicated by the presence of intact mucosa overlying a smooth mass When ulceration is present the differentiation is more difficult if not impossible The roentgenologic and gastroscopic demonstration of marked mucosal infiltration with swollen distorted folds is very suggestive of lymphoblastoma but a similar picture may be produced by infiltrative carcinoma or hypertrophic gastritis The gastric analysis is not significant nor is the presence or absence of occult blood in the stool important except as it betokens the presence of a bleeding lesion

Treatment —The treatment indicated in all cases is operation with resection of the stomach and removal of the tumor if possible In the infiltrative sarcomas and blastomas resection is often not feasible but a biopsy either of the tumor itself or a metastatic lymph gland perhaps a cervical gland is valuable Lymphoblastomas and malignant mesenchymal tumors in general tend to be very radiosensitive and hence surprising results may be obtained with radiation therapy

WALTER L PALMER.

EPITHELIAL TUMORS

BENIGN MUCOSAL NEOPLASMS

Definition.—Benign epithelial or mucosal neoplasms include adenomas papillomas and adenomatous polyps of various kinds The distinction between benign and malignant new growths is of course a relative one for most benign tumors are potentially malignant and some malignant tumors are relatively benign The relationship of these lesions to atrophic gastritis pernicious anemia and carcinoma, will be discussed further in the section on carcinoma (see descriptive legend of Fig 62) Benign gastric polyps are uncommon although not rare Clinically the great difficulty lies in proving that they are indeed benign and not malignant In fact this difficulty is so great and the danger that even a benign polyp may undergo malignant change is so definite that surgical removal is as a rule indicated The pedunculated adenomas are usually benign whereas the broad based papillomas tend to be malignant but the distinction is not reliable

Symptoms —Pain is as a rule absent or slight and present only if the polyp prolapses into or through the pylorus or is sufficiently large to be caught and pulled by gastric peristalsis The usual symptoms are those of anemia resulting from continued bleeding

Diagnosis —The syndrome of pernicious anemia may be simulated even to the extent of a high color index with definite macrocytosis Achlorhydria is almost invariably present The diagnosis is made by the roentgenologic or gastroscopic demonstration of a polyp (Fig 61) Pernicious anemia and

gastric polyposis may coexist On the other hand the chronic bleeding may very rarely produce a blood picture simulating primary anemia or the blood loss may modify the hematologic picture of pernicious anemia if it is present The demonstration of combined cord degeneration speaks positively for primary anemia Occasionally decision as to whether the two diseases coexist must be deferred until the polyp has been removed and the subsequent course of the blood picture studied

Fig 61—Pedunculated gastric polyp in various phases of prolapse through the pylorus The patient, Unit No 116743 a woman forty four years of age had had indefinite abdominal distress intermittently for several years with occasional attacks of vomiting There was no anemia

Treatment —Treatment consists of surgical removal The polyp may be excised and the base cauterized or a subtotal gastrectomy may be performed The advantage of the latter procedure is that it protects the patient against carcinomatous change in the mucosa adjacent to the polyp The prognosis is excellent

WALTER L PALMER

CARCINOMA

Incidence —Cancer of the stomach kills more people than any other cancer of the body and therefore ranks high among the common causes of death There are approximately 27 000 annual deaths from gastric carcinoma in the United States constituting about 18 per cent of the total deaths from cancer The incidence of gastric carcinoma is increasing due apparently to the rapid lengthening of the life span which has occurred during the past fifty or seventy five years Gastric cancer is almost unknown in the first decade of life rare in the second uncommon in the third decade and common indeed thereafter from the age of thirty five on It occurs among all races of mankind in all parts of the world It is unrelated to occupation position in life social status contact with other patients or trauma Heredity may be important for families are not infrequently encountered in which the incidence of carcinoma in the stomach or in other organs is extremely high On the other hand gastric cancer is not infrequently observed in individuals with no *known* history of cancer in the family

Etiology —The cause of carcinoma is still unknown but the gradually accumulating evidence seems to show that cancer is not congenital that it does not develop from embryonal rests that it is not directly inherited although a predisposition to it may be inherited that it is an acquired disease and that it is neither infectious nor contagious Filtrable viruses and various chemical carcinogenic agents are under active investigation as potential causes of carcinoma Trauma is of etiologic importance only as far as it relates to the sequelae of corrosion of the mucosa as in acid or alkali poisoning or to the effect of the carcinogenic chemical agents Gastric ulcer is generally considered to be a precursor of carcinoma but the evidence is most inconclusive This problem is discussed in detail in the section on gastric ulcer

Konjetzny and numerous other investigators contend that gastric carcinoma never develops in a normal mucosa and that it results from chronic atrophic gastritis with hyperplasia The essential process is not the chronic inflammation but the regenerative

Fig 62—Polypoid intraluminal gastric carcinoma Note the subtraction type of filling defect of the lesser curvature This case (X—No 32830) illustrates the entire subject of the possible relationship between atrophic gastritis pernicious anemia gastric polypus and carcinoma The pati nt a male fifty-eight years of age developed pernicious anemia in April 1926 responded well to the oral administration of whole liver *throughout the summer of 1926* was operated on in November 1926 because of the roentgenologic demonstration of a gastric tumor A pedunculated polyp 6 × 4 × 3 5 cm was removed the base being cauterized Sections of the polyp disclosed adenocarcinoma but no tumor *cells* were found in the pedicle The patient continued well although he found it necessary to use whole liver liver extract by mouth and later liver extract intramuscularly In the spring of 1934 the patient noted unusual hunger occurring before meals and at bedtime relieved by food X ray disclosed the polypoid intraluminal mass shown above Type I (Borrmann) A subtotal gastrectomy was performed in June 1934 a large fungating mass being *found* on the greater curvature of the stomach Histologically the tumor was found to be an alveolar colloid carcinoma A nodule was present in the serosal surface of the stomach at the site of the tumor and hence radiation therapy was administered postoperatively *The need* for persistent parenteral liver therapy has continued but in all other essential respects the patient has remained in excellent health for the past nine years and has now reached the age of 75

change in the epithelium resulting from the chronic gastritis In Konjetzny s extensive experience gastric carcinoma is always associated with such changes The transitional stages from chronic atrophic gastritis with small areas of hyperplasia to papilloma and carcinoma have been clearly shown. There is abundant evidence to prove that *carcinoma does not begin with a single cell.* but that many cells throughout an area of variable size may undergo malignant neoplasia Striking illustrations of these facts are seen in cases of multiple polyposis and frank multicentric carcinoma Chronic atrophic gastritis bears a fundamental relationship *not only to gastric polyposis and* carcinoma but also to pernicious anemia as has already been mentioned It is not yet clear whether or not the incidence of gastric carcinoma in cases of pernicious anemia under treatment is greater than should be expected in the age groups under consideration nor is *the effect of liver or liver extract* upon the gastric mucosa sufficiently known or understood although it has been established that definite improvement in the appearance of the gastric mucosa may occur after its administration

Gastric carcinoma then is an acquired disease developing in a pathologic gastric mucosa and probably arising on the basis of cellular reaction to continued injury or inflammation perhaps due to a toxin or infection but more probably due to some specific chemical carcinogenic substance or group of substances

Morbid Anatomy—Carcinoma *may* develop in any part of the stomach although fortunately for therapy the majority occur in or involve primarily the distal half or third There are many types of gastric carcinoma but for practical purposes the old classification of Borrmann and other pathologists *is helpful Four macroscopic types* may be distinguished as follows

1 The polypoid mushroom sharply circumscribed growth developing chiefly into the lumen of the stomach (see Fig 62)

2 The ulcerated circumscribed dishlike tumor with clearly defined borders (see Fig 63)

3 The ulcerated carcinoma with a definite wall or a sharp border on one side only not sharply circumscribed and infiltrating the gastric wall (see Fig 64)

4 The diffuse infiltrating type perhaps ulcerated superficially without definitely palpable borders and often with thickening of the wall of the entire stomach *(see* Fig 65)

Metastases tend to develop later in groups 1 and 2 than in groups 3 and 4 as expressed in the pathologic dictum Large primary growth, few metastases small primary growth many metastases'

The extent and the character of the ulceration may be affected by the gastric juice When acid gastric juice is present the base of the carcinomatous ulcer appears cleanly digested rather than necrotic and its edge tends to be sharp rather than ragged and indefinite The ulceration may rarely extend beyond the carcinoma into normal tissue and thus produce a lesion grossly indistinguishable from a benign ulcer

The *microscopic types* of gastric carcinoma are variable and are not to be correlated with the macroscopic forms All grades of differentiation are seen from the highly differentiated cylindrical adenocarcinoma to the poorly differentiated or almost entirely undifferentiated cellular carcinomas resembling sarcomas Broders classifies the malignancy of tumors on the basis of the degree of differentiation present histologically into the following four grades

1 Carcinoma cells 75 to 100 per cent differentiated

2 Carcinoma cells 50 to 75 per cent differentiated

3 Carcinoma cells 25 to 50 per cent differentiated

4 Carcinoma cells 0 to 25 per cent differentiated

The tendency is for *metastatic lesions* to develop most rapidly in poorly differentiated tumors least rapidly in the highly differentiated ones The spread takes place by way of the lymphatics the peritoneum or the blood Presumably metastases would occur in all patients if they lived long enough but at the time of autopsy the incidence of metastases is 14 to 25 per cent The adjacent lymph glands are usually first involved Infiltration of the supraclavicular node the so called Virchow s node is found in approximately 5 per cent at autopsy Hepatic involvement peritoneal and omental metastases and direct extension into the esophagus are all quite common

The neoplasm rarely extends beyond the pylorus into the duodenum Any adjacent organ may be involved by direct extension, particularly the pancreas liver colon spleen or diaphragm Peritoneal spread to the ovaries the so called *Krukenberg tumor* invariably involving both ovaries, occurs in approximately 5 per cent of the cases Similar implantation metastases occur in the male in the rectal pouch the so called rectal shelf of Blumer Pulmonary metastases are less frequent than might be expected Other rather rare but nevertheless definite sites of metastases are the navel skin brain, and bone marrow

Symptoms —The symptoms of cancer of the stomach are most indefinite almost any *indigestion* in any individual of cancer age is suspicious Gastric carcinoma is a disease to be kept always in mind and to be excluded only with care and hesitation The *onset* is indefinite the symptoms are slight the disease progresses so stealthily that it is neither suspected nor recognized until it is well advanced The *duration* of symptoms is variable usually it is a few months occasionally it is two or three years rarely it is several years and then of course question arises as to whether the early symptoms should not be attributed to some other cause If so the change in the distress picture may not be recognized by the patient Remissions in the distress are rare the course of the disease being almost invariably progressive

Usually the patient is an individual forty or more years of age who previously has enjoyed excellent health He first notices some *loss of appetite* and consequent *loss of weight* and a very *mild epigastric distress* These symptoms are disregarded for a few weeks or months but they progress and in less than a year he seeks the advice of a physician The weight loss then amounts to 10 or 20 pounds or more The loss of appetite is definite but the patient may not have noticed it The *abdominal distress* consists of fulness or discomfort induced by eating or of gnawing or aching epigastric pain which may appear at any time after eating which not infrequently is relieved by eating and usually is relieved by induced or spontaneous vomiting The pain may follow the identical pattern of peptic ulcer In many cases however the distress of carcinoma is notably different from that of peptic ulcer in that it is present in the morning before breakfast, appears soon after eating and is

not completely relieved by food taking alkali, or even vomiting *Nausea and vomiting* may occur regardless of the location of the lesion, but are much more frequent when the carcinoma obstructs the gastric outlet More or less intractable vomiting of food

Fig 63 —Carcinoma of the antrum Note the characteristic ragged irregular subtraction type of deformity of both curvatures of the antrum The tumor was an ulcerated but *sharply demarcated* (Type II Borrmann) alveolar carcinoma The patient (X—No 7,027) a man forty nine years of age was admitted to the *hospital* January 6 1930 for various symptoms attributed to anemia Loss of appetite and loss *of* weight amounting to 15 pounds had been present for six or eight months An epigastric tumor mass was palpable Moderate anemia occult blood *in the stool* and histamine achlorhydria were present The patient refused operation The loss of weight progressed Vomiting and diarrhea appeared in May and persisted until his readmission to the hospital in September after tarry stools had been present for four days At operation September 13 1930 no metastases were found and a subtotal gastrectomy was performed The patient survived a prolonged postoperative diarrhea and in December a double simple mastoidectomy He remained well until May 1936 when he returned because of malaise and loss of weight The cervical and inguinal lymph glands were enlarged and hard in consistency particularly the so-called Virchow s node above the left clavicle The involved glands were treated with roentgen irradiation but death occurred March 13 1937 over seven years after the diagnosis had first been made and six and a half years after resection of the carcinoma

and gastric juice may be the first symptom of small early intrapyloric tumors The vomitus may or may not contain food blood or bile although the so called coffee ground emesis is particularly suggestive of carcinoma *Hematemesis and melena* may be the first symptom of the disease or occur at any time during its course *Anemia* is often, but not regularly present is almost invariably of the secondary type unless concomitant pernicious anemia exists, and is due to the continual loss of blood from the surface of the tumor *Acute perforation* although uncommon does occur and the surgeon may not suspect the carcinomatous nature of the lesion at the time of the repair An elevation of temperature of 1° or 2° F is not infrequent More marked *fever* does occur and is attributed to a coincident pyogenic gastritis as is evidenced by the histologic demonstration of small abscesses or rarely even by the presence of a phlegmonous gastritis

Examinations —*Physical Examination*—The physical examination is often negative but it may reveal pallor evidence of loss of weight, a palpable movable hard mass in the upper abdomen usually independent of the liver a definite nodular enlargement of the liver a hard enlarged Virchow s node metastatic lesions in the ovaries or on the rectal shelf or rarely in tumors of the fundus of the stomach obliteration of Traube's semilunar space

Laboratory Examination —The laboratory examination may disclose the presence of anemia Free acid is present in the gastric content in about 40 per cent of the cases and after the injection of histamine hydrochloride subcutaneously may be found in rather high concentration 75 to 100 clinical units (*p*H 1 3-1 0) The demonstration of Oppler Boas bacilli and of abnormal amounts of lactic acid in the gastric contents is very strong evidence of gastric neoplasm for these findings occur only when continued retention or stagnation takes place in the stomach with no free acid present that is *with a pH above 3 a combination* of circumstances usually due to carcinoma Occult blood by the benzidine test is present in the gastric content and in the *stool* in 90 to 95 per cent of cases Stool examination therefore gives valuable diagnostic evidence regarding the presence of carcinoma but two possibilities must always be borne in mind first that occult blood if present may not be of gastric origin and second that carcinoma particularly of the infiltrative and scirrhous types may be present in spite of the continued absence of occult blood in the stool Indeed very rarely after massive hem

orrhage the occult blood in the stool may disappear completely for several weeks

X ray Examination —The x ray examination *is probably more valuable in the diagnosis* of gastric carcinoma than any other diagnostic method sign or symptom Although it is not infallible it is constantly improving in accuracy as technic and equipment become better and the proficiency of the roentgenologist increases The classic roentgenologic evidence of carcinoma is the filling defect a rigid constant somewhat ragged alteration in the contour of a portion of the stomach In the antrum both curvatures are likely to be involved and the lumen raggedly narrowed by the infiltration of the wall (see Fig 63) The polypoid tumor growing into the lumen appears as a non opaque nodular mass when pressure is made on the barium filled or partially filled stomach (see Fig 62) Ulceration may be evident from collections of barium caught in the ulcer and typically presenting the appearance of the so-called meniscus sign of Carman (see Fig 64) The normal mucosal pattern is almost invariably distorted or destroyed by the tumor as may be seen from careful mucosal relief studies using small amounts of barium and graduated compression

The roentgenologist not infrequently discovers a dilated stomach with hyperperistalsis yet with obstruction so complete that he is unable to see any barium pass through the pyloric channel and hence is unable to ascertain the exact location or nature of the lesion The problem in such a case is usually the differentiation of a pyloric carcinoma from a duodenal ulcer with high grade stenosis The obstruction is rather more likely to be complete with carcinoma than with ulcer and of course the duration of symptoms as well as the other diagnostic criteria are very helpful

In all cases *the roentgenologic evidence* must be carefully weighed and evaluated by itself and in conjunction with the clinical data

Gastroscopic Examination —Gastroscopy is of value in confirming the roentgenologic diagnosis of carcinoma or not infrequently in providing definite evidence bearing on a questionable roentgenologic finding Occasionally a tumor may be demonstrated with one method and not with the other Gastroscopy may give important information with regard to the type of the tumor its *operability and the prognosis* Gastroscopically, tumors are seen in picturesque forms and in colorings much more brilliant than those seen at autopsy or in the resected specimen The polypoid tumors are usually seen easily and are readily recognized although occasionally it is difficult to differentiate them from benign tumors or hypertrophic gastritis If ulceration is present however

Fig 64 —Ulcerating carcinoma of the lesser curvature The crater lying beneath the line of the lesser curvature is surrounded by the ragged nodular halo produced by the polypoid infiltrated wall The roentgenologic diagnosis was an ulcerating Type II gastric neoplasm the gastroscopic diagnosis was huge ulcerating Type III carcinoma of the posterior wall and lesser curvature Subtotal gastrectomy was carried out The tumor was a well localized ulcerating polypoid carcinoma measuring about 5 × 7 cm The patient, X—No 67633 a female forty four years of age had had left upper quadrant distress for six months and had lost 34 pounds in weight. The blood count was normal Histamine achlorhydria was present

the carcinomatous nature of the lesion is apparent for the irregular ulcer floor covered with pieces of necrotic tissue dirty *gray greenish gray brown red or violet in* color is surrounded by a thick wall usually dark red in color and sharply demarcated from the normal gastric tissue When the margin of the ulcer is seen to fade gradually into infiltrated tissue which in turn blends imperceptibly with the normal gastric mucosa the lesion is usually an infiltrating ulcerating tumor of Type III or IV Certain infiltrating carcinomas may be im

possible to differentiate gastroscopically from lymphosarcoma, lymphogranuloma, leukemia, syphilis or hypertrophic gastritis

Diagnosis—The importance of carefully examining all patients in middle life and beyond who have continued abdominal distress cannot be overemphasized The symptoms of carcinoma while usually suggestive, are *not diagnostic The physical and laboratory* examinations may yield corroborative, although as a rule not pathognomonic evidence The roentgenologic and gastroscopic examinations give more exact and precise information The diagnostic accuracy of the complete clinical study is very great—so great indeed that "exploratory laparotomy as a diagnostic procedure in gastric disease is rarely indicated In fact the evidence gained by palpation and inspection of the

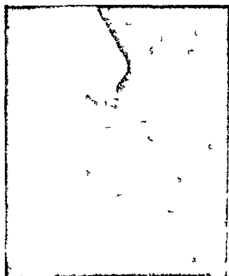

Fig 65 — Leather bottle stomach Note the small uniformly contracted stomach giving the appearance of a stomach in miniature the dilated esophagus and the rather well filled duodenum The patient (X—No 156548) a male fifty five years of age had had stomach trouble off and on for several years with swelling of the abdomen beginning two months prior to admission for which paracentesis was required Death occurred two months after the above roentgenogram was taken

stomach at operation may be less reliable than that obtained preoperatively

Course—The course of gastric carcinoma is invariably progressive the symptoms are likewise progressive although they may exhibit in rare instances remarkable fluctuations and remissions The *clinical course* of the disease usually covers a period of from twelve to thirty months but it may be only a few weeks, almost acute' or it may last several years, being in a sense 'chronic Death comes usually from inanition with prolonged anorexia vomiting and weakness

Prognosis—The prognosis depends upon the type and location of the tumor and upon the resistance of the individual It is important to know that in general the polypoid *sharply circumscribed neoplasms* growing into the lumen (Type I of Borrmann Moskowicz Konjetzny, Schindler) (see Figs 6? 63, 64) are much slower in their growth than are the infiltrative ones (Types III and IV) (see Fig 65) although exceptions do occur Some papillomatous carcinomas metastasize early, and conversely the infiltrating carcinoma fibrosum, producing the so-called linitis plastica may run a very slow course metastasizing late or not at all The diffusely infiltrating carcinomas of Jarcho on the other hand produce very small local lesions and metastasize early the metastatic tumors in the bone marrow or elsewhere giving rise to symptoms before the primary growth does so

The histologic grading of *malignancy* (Broders) may be helpful in that on the whole the degree of differentiation and the grade of malignancy are inversely proportional to each other Different sections from the same tumor however may disclose varying degrees of differentiation And indeed a highly differentiated colloid carcinoma may rarely be very malignant

The location of the neoplasm is of prognostic importance in several respects Carcinomas of the pylorus (intrapyloric tumors) produce obstruction and symptoms earlier than do those in the body of the stomach and are easily resected Tumors of the distal third of the stomach may be resected more easily than those of the middle *third* and these in turn are much more easily resected than those of the upper third or cardia Carcinomas of the greater curvature tend to be more easily resectable than those of the lesser curvature because the involvement of the deeper lymph glands occurs at a later stage in the disease and also because the primary growth is as a rule most accessible

The *resistance* of the individual to carcinoma is unpredictable but there is evi

dence that the body does exhibit a certain ability to resist or even destroy cancer cells Years after the resection of a gastric carcinoma cellular nests of carcinoma may be found locked in the scar tissue no other metastases being demonstrable

The prognosis is not influenced by sex and on the whole not greatly by age although in general carcinoma is said to progress more rapidly in the young more slowly in the aged However the longest cure in the Breslau clinic (twenty one years) was observed in a young man thirty one years of age The duration of life after resection of a gastric carcinoma averages one to two years longer than in cases treated with palliative medical measures only or indeed with other forms of surgery So called three year cures after resection are frequent five year cures are not infrequent and cures of longer duration do occur as in the case mentioned above

Treatment —There is at the present time only one real treatment for gastric carcinoma and that is surgical removal

Surgical Removal —CONTRAINDICATIONS TO OPERATION —There are available preoperatively very few criteria sufficiently positive to justify a decision against exploratory laparotomy— exploratory in the sense that the operation is undertaken to determine what can be done surgically Advanced age is not a contraindication for the operation is one not of choice but of necessity Weakness cachexia heart disease and other associated conditions likewise do not constitute contraindications Preliminary blood transfusions and parenteral clyses of normal saline in amounts of 2000 to 3000 cc daily usually bring sufficient improvement in the general condition of the patient to warrant operation within a few days Definite contraindications are limited to the presence of proved metastatic lesions such as a carcinomatous peritonitis neoplastic infiltration of the liver or metastases to the bone marrow Great caution is necessary for a nodular liver may be a cirrhotic liver independent of the gastric tumor

RESECTABILITY —The circumscribed polypoid Type I carcinomas are usually resectable whereas the infiltrative Types III and IV are more likely to extend along the esophagus or to involve adjacent structures such as the liver or pancreas The surgeon may be able to find a line of cleavage and remove the tumor but recurrent growths almost invariably develop The prognosis after resection is much better in Types I and II than in III and IV, except for certain rare exceptions such as the highly malignant papillomatous tumors on the one hand and the very slow growing carcinoma fibrosum on the other However regardless of the gross or histologic appearance all gastric carcinomas should if possible be resected even a complete gastrectomy being at times justifiable The presence of large lymph glands is not a contraindication to resection because the enlargement may be inflammatory rather than neoplastic and because life is usually prolonged by resection even if lymphatic spread has taken place Metastases in the liver or distant lymph nodes likewise do not necessarily constitute a contraindication to resection for the operation may prolong life even under these circumstances and may lead eventually to a less agonizing death than that resulting from pyloric obstruction In rare instances the patient may be definitely benefited by the removal of a gastric carcinoma and simultaneous extirpation of metastatic lesions elsewhere such as ovarian (Krukenberg) implantations

MORTALITY RATE —Existing statistics on operability and on surgical operative mortality are of little value because they are based upon three variables—the patient the surgeon and the tumor The mortality rate rises as the removal of the more extensive tumors in the more debilitated patients is attempted The best surgical risk is the individual with a small intrapyloric growth producing acute obstruction early If resection is undertaken only in cases of this type the mortality rate should be very low whereas if the surgeon undertakes to remove all carcinomas even though a complete gastrectomy is required, the hazard of the operation is necessarily greatly increased In some institutions a mortality rate of 10 per cent is arbitrarily considered satisfactory a lower rate indicating that too few resections are being undertaken and a higher rate too many Obviously the skill and experience of the surgeon influence both the percentage of cases in which resection is

attempted and the mortality rate It is important to emphasize the fact that the mortality rate alone is not a satisfactory index of immediate surgical results for it must always be evaluated in terms of the per cent of total cases submitted to operation and the per cent in which resection is attempted Exploratory laparotomy *per se* has a definite hazard and very little therapeutic value gastro enterostomy has a certain palliative effect, *resection* alone offers the patient the chance of a cure Consequently a high mortality rate with a high incidence of resection may be preferable to a low mortality rate with a low incidence of resection

Palliative Treatment—Various palliative procedures may be employed in inoperable tumors and in patients refusing surgical aid

GASTRO ENTEROSTOMY in inoperable obstructive tumors may give the patient an interval of six to eighteen months of fairly good health with symptomatic relief and a gain in weight before the inevitable decline again becomes manifest

RADIATION THERAPY has produced some striking morphologic changes in certain gastric carcinomas and has been found very valuable in the treatment of lymphoblastoma and other malignant mesenchymal gastric tumors but no satisfactory proof exists that it has ever cured a single case of gastric carcinoma The nausea, vomiting and weakness resulting from the therapy usually accelerate the downward course of the patient Radiation can therefore not be recommended either as a therapeutic or palliative procedure On the other hand the destructive effect of the roentgen ray on neoplastic cells cannot be denied and hence in time a means may be found for utilizing it in the prevention or treatment of gastric carcinoma The value of postoperative radiation after resection remains to be fully assessed but it seems to prolong the survival period

SYMPTOMATIC TREATMENT varies from day to day and from patient to patient Rules cannot be laid down The needs of the day must be met as they arise with the various diets drugs and procedures available but above all with kindness and sympathy and with as much encouragement and cheerfulness as possible The physician must endeavor to support the waning courage of the patient and thus help him carry on as bravely as possible

The *diet* should be palatable and nutritious Restrictions should not be imposed. In some cases particularly those with acid gastric juice the *antacid ulcer management program of Sippy* may afford partial or complete symptomatic relief for several weeks or months Suggestion and other forms of psychotherapy are occasionally strikingly effective for a short time Sedatives analgesics hypnotics and narcotics should be used unhesitatingly but judiciously The parenteral administration of fluid and rarely blood transfusions may be indicated

The Patient, the Physician, and the Truth—The difficult question as to whether or not the patient should be told the true nature of his disease cannot be answered categorically Patients and physicians have various opinions in this regard The patient with carcinoma is not likely to accept the truth if told it as philosophically as he himself had planned Certainly the patient should be told enough to ensure the proper treatment Usually it is sufficient to state simply that an operation is necessary for obstruction or for tumor A responsible member of the family should always be informed frankly and fully not only of the presence and nature of the disease but also of the prognosis and the therapeutic possibilities The word cancer should not be used to the patient and usually not to the relatives if it can be avoided for to most people it has only the most terrible connotations The fear of cancer is so great that many patients if told they have cancer immediately abandon all hope and in utter panic refuse to make any attempt to deal with it intelligently The public is not yet sufficiently aware that cancer may be curable The patient told that he has a 'growth may well understand that he has a cancer but he prefers not to press the point The responsible relative is more likely to do so and of course should be told If however the patient refuses operation and particularly if he does so when the physician considers that the tumor is *likely* to prove resectable the facts should be presented fully and frankly The patient may still refuse surgical treatment and it *is* his privilege to do so but usually he accepts

the advice given If he survives resection it is better not to inform him of the likelihood of recurrence If the tumor cannot be resected it is not necessary to tell the patient that he is doomed A certain vagueness leaves a ray of hope whereas complete frankness may be terribly brutal Honesty as a moral law does not justify brutality and honesty after all is purely relative The physician must remember also that mistakes are made that his diagnosis may be wrong and that strange things are seen in the practice of medicine Usually the situation can be handled in such a manner as to avoid frank discussion of the nature of the disease its course and prognosis The patient may fear the worst but usually he finds courage to hope that the condition is not as bad as he fears The physician with kindness sympathy, courage and resourcefulness must travel the road with the patient relieving his distress as much as possible and supporting his morale until finally the journey ends before the patient realizes that death is at hand

PEPTIC ULCER

(Digestive Corroding Eroding Simple Round Perforating or Acid Ulcer)

Definition —Peptic ulcer is a sharply circumscribed loss of tissue beginning in the mucosa extending through the submucosa into the muscular layers of the esophagus stomach or intestine and resulting from the failure of the mucosa to withstand the digestive action of acid gastric juice The first clear description is usually attributed to Cruveilhier (1829) whose name it bore for many years as the round ulcer of Cruveilhier" but Matthew Baillie pictured the lesion in a series of engravings published in 1799 and John Abercrombie wrote an excellent account of the symptoms in 1828

Distribution —The geographic distribution of peptic ulcer is world wide the lesion occurs in all races of men The incidence of the lesion is reported to vary in different countries but the statistics are open to question It occurs among all occupations, workers and nonworkers

Incidence —The exact incidence of peptic ulcer in man is unknown although it is estimated on the basis of autopsy statistics that approximately 10 per cent of all individuals suffer at some time in their lives from a chronic gastric or duodenal ulcer At autopsy the gastric lesion is more frequent than the duodenal but duodenal ulcer is much more commonly encountered clinically For some unknown reason, males are afflicted about four times more frequently than females

The lesion occurs at all *ages* Acute ulcers producing melena neonatorum and acute perforation are not uncommon in the newborn Unless these complications are present chronic ulcer is rarely diagnosed during the first decade of life although its incidence is probably greater than is generally appreciated Between the ages of twenty and fifty peptic ulcer is very common after fifty it is also frequent Striking instances of an *hereditary* or *familial tendency* are encountered but perhaps not more often than might be expected on the basis of coincidence The typical ulcer patient is usually described as a lean individual of a definite *constitutional type* contrasting with the short stocky obese so called gallbladder type As a matter of fact peptic ulcer and cholelithiasis are seen in all constitutional types and not infrequently in the same individual

Morbid Anatomy —*Location* —Peptic ulcer occurs in the lower part of the esophagus in the stomach in the upper portion of the duodenum in the small bowel adjacent usually to a patent gastro enterostomy or a Meckel s diverticulum and very very rarely elsewhere in the jejunum or ileum The lesion occurs in constant association with normal or ectopic gastric mucosa The vast majority of peptic ulcers occur along the

lesser curvature of the stomach, the so called 'magenstrasse,' or in the first 3 or 4 cm of duodenum the duodenal bulb The pylorus is not infrequently involved, prepyloric and postpyloric lesions are rather common The greater curvature of the stomach is a very rare site for benign ulcer

Pathologic Description—Ulcers are usually single but not infrequently they are multiple being present in both the stomach and duodenum or as multiple lesions in either organ such as the so called kissing ulcers of the anterior and posterior walls of the duodenum Active and healed lesions may coexist The average diameter of the gastric ulcer is 5 to 25 mm, although the lesions may be only 2 or 3 mm in diameter or as large as 40 to 60 mm In the duodenum and jejunum the diameter usually varies from 2 to 10 mm, rather rarely reaches 15 mm and quite rarely 20 or 30 mm The depth is variable often 10 to 20 mm in the stomach, usually 2 to 6 mm in the duodenum The lesion differs from an erosion in that it involves not only the mucosa but also the muscularis mucosae Peptic ulcer is the result of a penetrating process beginning in the mucosa invading the deeper layers of the gastric wall and perhaps, perforating them completely It may be acute or chronic the essential difference pathologically being the amount of connective tissue present The border of the ulcer is sharp the surrounding mucosa may be normal or slightly inflamed flat or slightly elevated or even rounded due usually to extensive edema of the submucosa or rarely to fibrous tissue The floor of the ulcer is clean and consists of a thin layer of fibrinopurulent exudate overlying a narrow zone of fibrinoid necrosis and a deeper zone of granulation and fibrous tissue In chronic ulcer the muscular layer in the base is usually interrupted completely by fibrous tissue and the blood vessels are thrombosed The capsule of the liver or pancreas may form the base of the ulcer, or indeed the lesion may invade these organs Evidence of extension and healing may be found together although usually ulceration or repair is dominant at a given time the one leading to further ulceration perforation or hemorrhage and the other to quiescence and healing with scar tissue proliferation growth of a thin layer of mucosal cells across the defect and the eventual transformation into a normal mucosa The life history of an ulcer with its characteristic periods of remission and exacerbation is thus evidenced pathologically by phases of more or less extensive ulceration and more or less complete healing

Carcinomatous Degeneration of Benign Ulcer—The subject of carcinomatous degeneration in peptic ulcer has been a very controversial one as regards both its occurrence and its alleged incidence The question arises in connection with gastric ulcer only Primary carcinoma of the first portion of the duodenum is very rare although carcinoma elsewhere in the duodenum is not so rare Carcinoma of the jejunum adjacent to a gastro enterostomy stoma is also so rare that the question of malignant degeneration of a jejunal peptic ulcer has scarcely arisen Although various explanations have been given for the alleged tendency of gastric ulcers to undergo malignant transformation in contrast with duodenal ulcer the evidence available suggests that benign peptic ulcer does not undergo malignant degeneration at all, but that gastric carcinoma on the other hand does at times undergo peptic digestion and may mimic the benign lesion in almost every respect This explanation is in accord with the high incidence of gastric cancer the almost complete absence of primary carcinoma of the bulb and the rarity of carcinoma of the duodenum and jejunum There is clear evidence that peptic digestion may almost completely destroy a gastric carcinoma and produce a lesion grossly identical with benign ulcer It must be admitted on the other hand that the possibility of carcinomatous degeneration of a benign ulcer cannot be denied even though proof of its occurrence is lacking From the practical point of view however the consideration is of very little significance in comparison with the question as to whether a given lesion is benign or malignant The important problem is the differentiation of the two lesions

Curling s Ulcer—Curling s ulcer is a special lesion an acute gastroduodenal ulceration following extensive burns of the skin The phenomenon was described by Swan in 1823 and later by Lang but Curling called attention to it

sexes at all ages, usually near the pylorus may be single or multiple usually causes pain nausea and vomiting within a few days after the burn and may be complicated by acute perforation or hemorrhage The lesion is as a rule not diagnosed clinically but is found at autopsy In rare instances a chronic ulcer may result The mechanism of production is unknown It may be related to an increased gastric secretion as a result of a systemic histamine reaction secondary to the burn

Association with Other Diseases—Peptic ulcer occurs in conjunction with practically all diseases the notable exceptions being those characterized by a complete achlorhydria particularly pernicious anemia and combined column degeneration of the spinal cord In the milder grades of atrophic gastritis acid gastric secretion and peptic ulcer may be found but in the more severe forms achlorhydria usually obtains and peptic ulcer is not present Superficial and especially hypertrophic gastritis are commonly found in patients with ulcer Gastric carcinoma or neoplasm of any type located anywhere in the body may be observed coincident with active or healed ulcer Special reference should be made perhaps to the lesions occurring in patients with tumor of the brain particularly after operation although their exact frequency and significance are open to question Primary secondary tertiary and latent syphilis including tabes dorsalis and general paresis are seen in approximately their anticipated frequency in patients with ulcer Polycythemia thrombo angiitis obliterans heart disease of all kinds essential hypertension pulmonary tuberculosis as well as all acute and chronic infectious diseases hyperthyroidism and diabetes mellitus—all occur in patients with peptic ulcer or vice versa In pregnancy ulcer rarely develops and the symptoms of ulcer if present previously usually subside In diaphragmatic hernia erosions or ulcers are likely to develop at the constricting ring Occasionally ulcer is seen in patients with hepatic cirrhosis the incidence is not significant nor is that of ulcer with cholelithiasis Duodenal stasis as evidenced by a rather wide descending or second portion of the duodenum with so called puddling and reverse peristalsis is a phenomenon seen frequently in normal individuals in fact it is almost invariably present in patients with long thin abdomens and a narrow costal angle and hence is frequently observed in patients with peptic ulcer Renal calculi appear to be somewhat more frequent in patients receiving alkali therapy for peptic ulcer than they are in normal persons although this point is not definitely established Acute appendicitis is a common complication of antacid ulcer management due presumably to the formation of enteroliths in the appendix followed by obstruction and resultant increase in the intraluminal pressure as shown experimentally by Wangensteen

Etiology and Pathogenesis—Peptic ulcer has been ascribed to various causes including bacterial and nonbacterial inflammation trauma infarction chemical action and neurogenic mechanisms

Bacterial Inflammation—Acute ulcers are found not infrequently at autopsy in patients dying from acute infectious disease but thus far all attempts to isolate a specific micro organism have been unsuccessful Various bacteria have been isolated from the floor and acute lesions have been produced by the injection of different organisms but typical chronic ulcer results only occasionally not with convincing regularity

Nonbacterial Inflammation—The concept of nonbacterial inflammation as the cause of ulcer is supported chiefly by the histologic evidence of chronic nonspecific gastritis so called antral gastritis in all cases of peptic ulcer Indeed cases have been described pathologically as ulcer disease without ulcer with symptoms indistinguishable from those seen in patients with ulcer There are certain objections to this theory one of the major ones being that gastroscopic evidence of gastritis is frequently lacking in patients with peptic ulcer Furthermore if gastritis were shown to be the forerunner of ulcer the cause of the gastritis would remain to be explained

Trauma—Direct epigastric trauma is occasionally followed by the prompt appearance of the symptoms of ulcer and indeed by its subsequent roentgenologic demonstration but there is no other evidence that it plays any role in the pathogenesis in the vast majority of cases

Infarction—The concept of vascular occlusion as the cause of ulcer is based on the craterlike appearance of the lesion and the demonstration of thrombosed vessels in the base Unsatisfactory hypotheses such as vascular spasm are advanced to explain the thrombosis, although this is apparently the result rather than the cause of the lesion It is not possible to produce chronic ulcers by ligation of the gastric vessels, for approximately 90 per cent of the blood supply to the stomach may be interrupted without producing necrosis of the mucosa

Peptic Digestion—The chemical theory of ulcer formation is based on the recognized ability of the gastric juice to digest living tissue as shown by Claude Bernard s classic experiment with the frog s leg Many theories have been offered to explain the normal ability of the gastric mucosa to resist digestion but apparently the thin layer of mucus constantly secreted by the mucus secreting cells affords the chief protection The evidence that chronic peptic ulcer is in some way related to acid gastric juice seems conclusive Clinically, chronic ulcer is found only in those portions of the digestive tract exposed to the action of acid gastric juice Furthermore it is found only in individuals whose gastric glands are able to secrete acid It is a highly significant fact that the 10 per cent of the population with histamine achlorhydria do not develop ulcer Experimentally ulcer may be produced by various operations interfering with the normal neutralization of the acid by the duodenal content by the administration of acid or by the continuous stimulation of acid gastric secretion by means of the intramuscular injection of a mixture of histamine and beeswax The pathologic clinical and experimental evidence are in accord in indicating that peptic ulcer is a penetrative process beginning in the mucosa and dependent upon the destructive action of acid gastric juice The explanation of the failure of the mucosa to withstand the acid attack is not clear

Neurogenic Theory—The neurogenic theory of ulcer formation has been advanced because ulcers are so frequently seen in nervous individuals or in relationship to emotional disturbances because the lesion is occasionally observed as a postoperative complication in patients with brain tumors and because acute erosions and ulcerations in the stomach follow the experimental production of certain intracranial lesions The explanation of these observations is not clear

Summary—Peptic ulcer is the product of pathologic physiology, it results from the failure of the mucosa to resist the destructive action of acid gastric juice The factors responsible probably include lack of cellular resistance a lack of cellular protection, as might result from an insufficient secretion of mucus or excessive acid gastric juice particularly during the night and during the fasting periods when the normal stomach secretes very little acid The central nervous system through the vagus may play a very important role by the production of hypermotility and quantitative hypersecretion These basic problems remain to be elucidated

Symptoms—*Pain* is the outstanding symptom of ulcer A thorough understanding of the distress of peptic ulcer is in the words of Sippy, the key to the analysis of abdominal pain The four characteristic features of the pain of peptic ulcer are its *chronicity* its *periodicity* its *quality* and its *relationship to food taking*

The CHRONICITY of the disease is indicated by the fact that the average stated duration of the distress is six or seven years in occasional cases the symptoms are of only a few days or weeks duration in others they may have existed for forty or fifty years

The PERIODICITY of ulcer distress is striking The usual statement is that the attacks come in the spring and the fall As a matter of fact the greatest incidence occurs in the months from October to March inclusive with an additional peak in June The significant point is not the season of the year but the periodicity of the distress The symptoms may last for a few days several weeks or several months and the periods of remission be of similar duration As time goes on the tendency is for the periods of distress to become more frequent and of longer duration whereas the remissions are less frequent and shorter *Precipitating* causes of the exacerbations are usually listed as acute infections, worry and fatigue although Moynihan included exposure to cold getting

the feet wet or the eating of a hasty and indigestible meal These unavoidable accidents of living are so common and so universal that one doubts their causal relationship to the formation or reactivation of an ulcer

The QUALITY of ulcer distress although rather variable tends to conform to a definite pattern It is as a rule a gnawing or aching sensation sometimes it is described as burning hurting annoying or cramplike or indeed as hunger It differs from the intermittent pang of true hunger in that ulcer distress is almost invariably steady and continuous for periods of fifteen minutes to an hour or more unless measures are taken to give relief Moynihan referred to ulcer pain as a hunger pain purely because of its relationship to food taking In severity the pain varies from a very mild discomfort to acute pain It is almost invariably epigastric usually sharply localized to an area a few centimeters in diameter to which the patient points with the tips of the fingers The pain may radiate around the costal border or through to the back or to the right lower quadrant or very rarely to the navel or below In duodenal ulcer the distress is likely to be located in the right epigastrium in gastric ulcer in the left epigastrium and in jejunal ulcer in the left mid abdomen or even in the left lower quadrant The presence of pain in the back suggests but does not prove the presence of chronic perforation

The *rhythm of pain* in peptic ulcer is related to the digestive cycle and is the same for both gastric and duodenal ulcer A detailed analysis of a typical day provides valuable information and should be incorporated in the history Pain attributable to ulcer is almost invariably absent in the morning before breakfast appears one to four hours after breakfast and lasts thirty minutes or more perhaps until relief is obtained at the noon meal The distress recurs one to four hours later and is then usually more severe than in the forenoon The afternoon pain may likewise disappear spontaneously but more frequently definite measures are employed to bring relief the patient having learned that the taking of food or alkali in adequate amounts vomiting or rest usually affords relief In the evening the pain may recur one to four hours after eating but it is often less severe than in the afternoon The same measures give relief The patient may be awakened with pain usually between 12 and 2 A M Rarely does nocturnal pain appear unless pain has been present in the evening and rarely indeed does pain attributable to ulcer develop later in the night unless it has been present earlier and relieved by food or alkali The presence of nocturnal pain is often interpreted as evidence of pyloric obstruction or high grade stenosis but it is also seen in nonobstructive acutely inflamed lesions with highly acid gastric secretion

Mechanism of Pain in Peptic Ulcer—The normal gastric mucosa is insensitive to cutting pinching tearing or exposure to varying hydrogen ion concentrations The inflamed mucosa on the other hand may be sensitive due apparently to a lowering of the pain threshold The pain of peptic ulcer depends primarily therefore, upon the degree of inflammation present in or about the lesion An acutely inflamed ulcer is highly sensitive to mechanical or chemical trauma in the form of peristalsis and spasm or changes in the hydrogen ion concentration The role of acid gastric juice in the pathogenesis of peptic ulcer has already been presented but it is important to point out that the acid juice evokes a chemical inflammation in the mucosal defect lowers the pain threshold of the nerve endings and produces pain When the defect is protected from the action of the acid the inflammation subsides the sensitivity decreases and the pain disappears The pain seems to arise directly at the site of the lesion not in some distant part of the stomach or duodenum or through any vague reflex mechanism The importance of the acid factor in the mechanism of pain in peptic ulcer is shown by the following observations

1 When pain attributable to ulcer is present a high degree of free hydrochloric acid is practically always found in the stomach

2 The pain is relieved by any measure which neutralizes the acid

3 The pain may be relieved by emptying the stomach and in sufficiently sensitive lesions be caused to reappear by reinjection of the acid chyme whereas the injection of the gastric content in which the free acid

ity has been neutralized does not produce pain

4 Ulcer pain typical in kind location and severity, may be produced under suitable conditions by the injection into the stomach of dilute solutions of hydrochloric acid in perfectly physiologic concentrations (0 2–0.3 per cent)

5 Ulcer pain under proper conditions may be induced by the injection of acid gastric juice from another patient or by stimulation of the patient's own gastric secretion by histamine

The concentration of acid at the time of the pain is not abnormal nor is it greater than that present in the same stomach without pain when the ulcer is healed or in a healing phase The presence of pain at any given moment therefore, is dependent upon the presence of an inflamed lesion and acid gastric juice Theoretically the former could occur without the latter practically it does not and probably for the reason that the inflammation of peptic ulcer results from the continued action of acid gastric juice The question is often raised as to why ulcers may be present may bleed profusely and may perforate without antecedent pain The only apparent answer is the rather vague and unsatisfactory one of a high pain threshold and low sensitivity

Atypical Distress—The classic ulcer history as outlined is frequently not obtained The usual reason is that the patient is a poor observer or insufficient care has been taken in describing the symptoms When a careful diary is kept or when the patient is hospitalized and the sequence of pain studied, it almost invariably conforms to the description given Exceptions occur in acutely inflamed lesions presumably with more or less *perigastritis* and *periduodenitis* In such cases the pain may be only partially relieved by food taking or by alkali or by the emptying of the stomach the incompleteness of the relief being due to a persistent soreness and tenderness which disappears in a few hours or days if neutralization of the acid is maintained

The so called *biliary* or *tabetic* types of ulcer distress in which there is a severe steady continuous pain accompanied by vomiting and simulating both biliary colic and the gastric crisis of tabes dorsalis constitute an important variant of the usual picture The attack may last for several days with continued pain nausea, and vomiting The vomitus consists of clear or bile-colored *highly acid* gastric juice in marked contrast with the viscid emesis of continued biliary or tabetic vomiting Slight jaundice is occasionally seen with peptic ulcer, presumably due to cholangitis

Accessory Symptoms—NAUSEA is not a common symptom of ulcer, although it may occur and not be accompanied by pain

EMESIS may result from severe pain, although usually the vomiting is caused by obstruction—spastic inflammatory, or cicatricial Painless vomiting may occur in high grade obstruction or more rarely in nonobstructive lesions in which case it is presumably due to a reflex disturbance of the intrinsic neuromuscular coordination

WATER BRASH is a rather rare symptom consisting of a combination of excessive salivation and acid regurgitation sometimes awakening the patient at night

The APPETITE and WEIGHT are usually well preserved but marked loss of weight, amounting to 30 to 40 pounds may result from continued vomiting or the patient's fear of eating On the other hand the frequent ingestion of food in order to relieve the pain may result in a gain in weight

CONSTIPATION is a common complaint usually associated with a cathartic habit the symptoms of which may completely obscure the distress of ulcer

DIARRHEA is rare except in the presence of a gastrojejunocolic fistula which may develop gradually or suddenly after gastroenterostomy and without any pain whatsoever The SIGNS AND SYMPTOMS OF ANEMIA may or may not be present in peptic ulcer if present they may develop gradually or acutely Occasionally chlorosis is erroneously diagnosed in such cases

Examinations —*Physical Examination*—In peptic ulcer the anamnesis is everything the physical examination nothing (Moynihan) although of course even negative findings are important Localized tenderness is not uncommon occasionally the outline of a distended stomach may be made out and peristaltic waves observed very rarely a tender mass may be palpable

Laboratory Examination—As in the

physical examination normal conditions are to be anticipated unless some complication is present The demonstration of acid gastric juice is essential because chronic peptic ulcer does not occur in its continued absence Sarcinae or yeastlike organisms in the gastric content are indicative of long con

Mistakes are made however both of omission and commission The roentgenologic evidence must be weighed and its value assessed by the clinician in conjunction with the other data available

The roentgenologic signs of ulcer are usually divided into the direct or primary signs

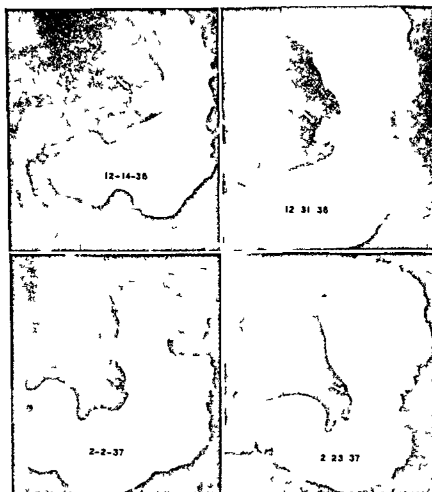

Fig 66—Spectacular healing of gastric ulcer The enormous crater present December 14 1936 was barely visible February 23 1937 Gastroscopically the lesion appeared to be almost healed at this time but complete disappearance was not reported until April 7 1937 The patient Unit No 165135 a female sixty three years of age gave a history of epigastric pain radiating through to the back between the shoulder blades unrelated to food relieved only by emesis and accompanied by more or less persistent vomiting for sixteen days Periodic postprandial epigastric distress had been present for eleven months and several similar attacks had occurred in the preceding thirty five years

tinued obstruction Occult blood may be found in the gastric analysis or in the stool but it is more often absent than present

X ray *Examination*—In peptic ulcer the x ray is the most important diagnostic procedure In proper hands and under suitable conditions probably 95 per cent of all ulcers may be demonstrated roentgenologically

and the indirect or secondary The *primary signs* are relatively pathognomonic and consist of the demonstration of the crater of the ulcer or the deformity produced by it or both whereas the *secondary signs* consisting of such nonspecific findings as gastric retention altered peristalsis and localized tenderness are relatively unimportant In

the stomach the crater is usually seen as a penetrating niche in profile (Fig 66), whereas in the bulb it is more frequently seen *en face* (Figs 67 69) The crater is the only definite roentgenologic evidence of active ulcer It can be demonstrated in at least 90 per cent of the cases of active gastric ulcer in from 50 to 70 per cent of those with active duodenal ulcer and probably in the majority of cases of anastomotic ulcer True craters may occur at any point along the lesser curvature of the stomach in the ture is seen, whereas in the duodenum the process typically causes some contraction and hence a deformity of one or both curvatures of the bulb (Figs 68 69)

Gastroscopic Examination —This method enables one to inspect the gastric mucosa and often permits the demonstration of small lesions not visible roentgenologically Its great disadvantage lies in its inability to see beyond the pylorus

Diagnosis —The diagnosis of peptic ulcer is based upon the clinical syndrome de-

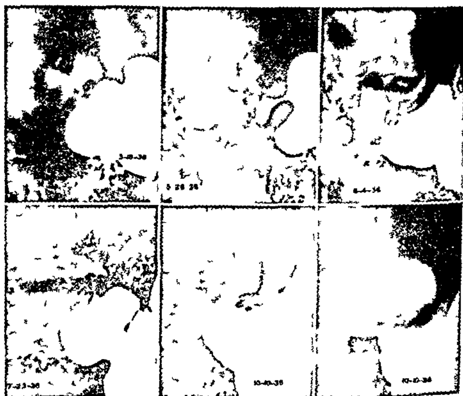

Fig 67 —Active duodenal ulcer showing an *en face* view of a large crater in an undeformed bulb Under treatment the crater decreased rapidly in size from May until October and in healing left no residual evidence of deformity The patient, X—No 48157 a male university student, nineteen years of age had experienced dull aching epigastric pain coming on three or four hours after eating for only three weeks before his admission to the hospital

bulb or even in the proximal part of the second portion of the duodenum In profile the crater appears as a penetrating niche *en face* it is a sharply outlined and circumscribed collection of barium usually 2 to 10 mm in diameter and surrounded by a clear halo The rugae or gastric and duodenal folds typically radiate to it As the ulcer heals its site may be indicated by the radiating folds In the stomach healing rarely alters the contour of the organ except in those cases in which an hour glass contrac

scribed and upon the direct roentgenologic or gastroscopic demonstration of the lesion The greater the skill of the roentgenologist the less the frequency with which a positive diagnosis will be justified without confirmatory roentgenologic evidence The differential diagnosis of a demonstrable gastric or duodenal lesion is usually not difficult for the criteria described are on the whole quite characteristic The most difficult task actually encountered is the differentiation of benign and malignant gastric ulcer

Differentiation of Benign and Malignant Gastric Ulcer—The criteria available for the differentiation of these two lesions are of relative not absolute value There are certain signs as pointed out previously more or less diagnostic of gastric cancer whereas there are none pathognomonic of a benign process unless it be the proved healing of the lesion Age is of some importance although carcinoma may occur in the third decade and benign ulcer is not uncommon in the sixth and seventh A long history of several years duration suggests a benign lesion and a short one malignancy but carcinoma may arise in a patient with chronic indigestion of whatever cause and conversely benign ulcer often develops acutely and gives a short history A qualitative or quantitative change in a chronic distress is sometimes considered as evidence of malignancy but this occurs in a benign lesion also Periodicity is usual in ulcer rare in carcinoma The relationship of the distress to food taking alkali or emesis so classically typical of peptic ulcer is likewise frequently seen in carcinoma Loss of appetite is much more likely to occur in cancer although marked loss of weight and strength may occur in both conditions Hematemesis coffee ground vomitus and melena may be the initial symptoms in either The continued presence of occult blood in the stool after two or three

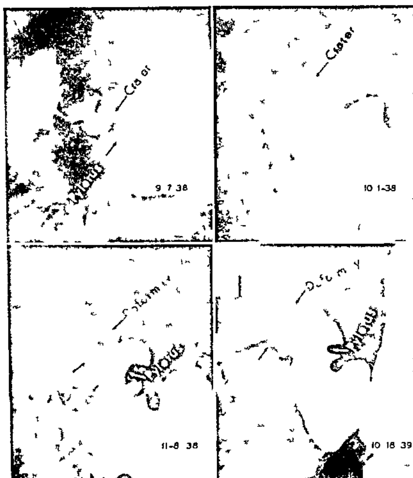

Fig 68—Healing duodenal ulcer Note the marked decrease in the size of the crater as seen in the compression views between September 7 and October 1 The residual deformity is well seen in the film of November 8 The apparent increase in the width of the channel between November 8 1938 and October 18 1939 is more apparent than real for the film obtained November 8 shows the bulb in a phase of contraction whereas that of October 18 shows a filled, although deformed bulb The patient X—No 68292 a male twenty three years of age had had epigastric distress for five years and several massive hemorrhages Histamine free acidity 115

weeks of careful treatment is presumptive evidence of malignancy whereas the continued absence of occult blood suggests that the lesion is benign although exceptions of both kinds occur The demonstration of histamine achlorhydria speaks almost unequivocally against a benign ulcer as does the presence of large numbers of Oppler Boas bacilli and lactic acid High acid values such as 100 or 110 after histamine (pH 1 0) are not infrequently seen in carcinoma

The *x-ray interpretation* of the nature of a gastric ulcer is valuable it depends upon certain considerations such as location size and depth relationship to adjacent structures and the character of the surrounding mucosal pattern Ulcers of the greater curvature are almost always malignant Indeed the greater the distance of the lesion from the lesser curvature the greater is the probability of its being malignant but on the other hand many ulcers of the lesser curvature are also malignant Size is of relatively little value, for small lesions may be carcinomatous and large craters are often benign The meniscus sign of Carman consisting of an ulcer crater located beneath the level of the lesser curvature and demarcated by a zone of tumefaction appearing as a halo almost invariably denotes carcinoma for benign craters usually extend beyond the lesser curvature (Compare Figs 64 and 66) The halo however may be seen in both lesions due either to inflammatory swelling and edema or carcinomatous infiltration or both The rugae about a benign ulcer tend to converge or radiate in a star like fashion, whereas in a carcinomatous ulcer they may be abruptly interrupted Benign craters are usually smooth or slightly irregular whereas malignant craters tend to be ragged and markedly irregular, but exceptions of both types occur And last, but not least, under suitable therapy the crater of the benign ulcer diminishes rapidly in size and disappears completely whereas carcinomatous craters decrease slightly and very rarely disappear completely—assuming a careful examination and reliable technic

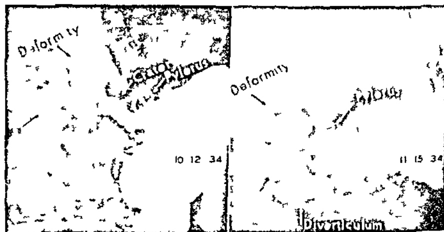

Fig 69—Marked deformity of both curvatures of a large duodenal bulb although the lumen is still quite adequate Between the pylorus and the deformity the duodenal bulb is rather ballooned out, producing a diverticulum like appearance The crater is usually found at or just proximal to the deformity In this case the crater is immediately beyond the pylorus (left view) A month later no evidence of crater was found although the deformity persisted The patient Unit No 103205 a male forty years of age had "stomach trouble of the classic ulcer type for ten years

The *gastroscopic interpretation* like the x ray is of great differential value in skilled hands but it is not infallible The benign ulcer according to Schindler ' is generally crater like rarely shallow, its floor is whitish yellow not often brownish in color although after an acute hemorrhage it may be dark red its edges are sharp often partly undermined The adjacent mucosa in early lesions is often normal later there may be marked inflammation of the surrounding mucosa but rarely of the entire stomach Converging folds occur The carcinomatous ulcer however is characterized by less sharp edges so that the ulcer floor seems to blend with the mucosa The floor is irregular and contains nodules nodes or ridges *It is* occa

sionally whitish or yellowish in color but more frequently brown brown red violet gray or a dirty color The malignant ulcer is usually elevated and appears to lie on a hill thus differing further from the benign ulcer The adjacent mucosa may be nodular'

The various criteria outlined must be carefully evaluated in the consideration of any given case The evidence may be sufficient to justify either a definite or a presumptive diagno is of neoplasm and hence to indicate treatment as such or it may be adequate to warrant a tentative diagnosis of a benign ulcer and provisional medical management but conclusive clinical proof that the lesion is benign is obtained only by the roentgenologic and gastroscopic demonstration of complete healing A sharply circumscribed penetrating lesion of the lesser curvature occurring in a stomach known to secrete acid gastric juice may be treated medically if its course is carefully studied Relief from pain and gain in weight are to be expected and in themselves are not very reassuring but continued distress may be significant The occult blood should disappear from the stool in two or three weeks if the lesion is benign and should continue if it is malignant but exceptions occur If roentgenologic and gastroscopic studies made at weekly or biweekly intervals show that the crater is decreasing rapidly in size and if it appears benign medical treatment may be continued in the expectation that complete healing will be demonstrable within a few weeks If on the other hand it changes very little or appears to be malignant a presumptive diagnosis of carcinoma should be made and subtotal gastrectomy be carried out if possible without further delay

Prognosis —The prognosis in peptic ulcer is excellent for the immediate attack but poor for the future in that recurrence is the rule The course of the disease is characterized by remissions and exacerbations The cures for peptic ulcer are therefore infinite in number for it is very easy to be misled by the therapeutic fallacy and draw the erroneous post hoc ergo propter hoc conclusion

Treatment —*General Considerations* —The therapy of peptic ulcer is essentially medical surgery if indicated is usually undertaken for the complications of ulcer less frequently for the lesion itself The problem may be divided into two distinct phases first the healing of the ulcer and second the prevention of recurrence On the whole the former is accomplished very much more easily than the latter In fact healing frequently occurs spontaneously Medical treatment cannot actually heal an ulcer it can only endeavor to create the best possible conditions for the process of healing and thus facilitate it Nature heals the ulcer Complete healing exists only when the defect is closed and covered with a normal glandular mucosa It is not possible for the clinician to know when this has occurred but obviously it is at least many weeks after the disappearance of pain of occult blood from the stool and the vanishing of the roentgenologic crater Treatment should therefore be continued for several months

A further reason for prolonged treatment is the recognized tendency of ulcers to recur at the same site or a different site even after complete healing has taken place and regardless of the type of medical or surgical treatment employed

Rest is essential in the treatment of many diseases in ulcer it is very valuable but often difficult to obtain The rest should be if possible both physical and mental the latter being even more important than the former Occasionally a strenuous hunting or fishing trip proves more restful than a period of bed rest Vacations often bring clearer perspectives and better attitudes

Psychotherapy is essential As a rule the superficial psychotherapy and encouragement incident to the medical program to be outlined is adequate Frequently sedatives such as phenobarbital and sodium bromide are of value In certain cases formal psychiatric care perhaps including detailed and prolonged psychoanalysis may prove helpful but unaccompanied by other medical treatment it is not adequate therapy even though a remission of symptoms ensues

Hospitalization with proper management is usually preferable to a vacation in the treatment of ulcer Meticulous attention to the detailed program of therapy to be described not only creates the best conditions for the healing of the ulcer but it is of

great psychotherapeutic value in establishing *the patient's confidence in himself*, in his treatment and in his doctor. In the hospital the patient learns that his condition is not unique, that the program of treatment can be carried out and learns how to do it. Two weeks of hospitalization or of rest in bed at home is usually the minimum period permissible. In difficult cases, a month or six weeks may be much more satisfactory, and occasionally a period of six months is desirable. Bathroom privileges may be allowed. The course of the lesion during this time should be determined at intervals by roentgenologic or gastroscopic studies. If possible, the patient should be kept away from work until the crater has disappeared. He must understand that he is confronted with a twofold problem: the healing of an ulcer and the prevention of its recurrence, and that certain restrictions and regulations of his life will be in order for an indefinite period, perhaps for life.

Acid Neutralization.—RATIONALE.—Sippy was the first to develop a program of therapy based on the premise that "the greatest known hindrance to the healing of peptic ulcer that is amenable to medical or surgical control ... is the disintegrating and digestive action of the gastric juice." Once this is removed, "Nature ... fills in the defect with granulation tissue and cicatrization of the ulcer may occur approximately as rapidly as it does elsewhere on other surfaces of the body." Sippy considered "peptic activity" to be the deleterious agent and attempted to neutralize the hydrochloric acid in order to inactivate pepsin. It is now known that the acid itself is more destructive than the pepsin, but in all other essential respects the extensive investigations of the subject carried out in the past two decades have corroborated the original concept of Sippy. If it were possible, practical and feasible to bring about complete and permanent gastric anacidity, there would be no ulcer problem. Unfortunately, there is no satisfactory method of attaining this goal. The Sippy treatment "aims however at 'maintaining an accurate neutralization of all free hydrochloric acid during the time that food and its accompanying secretion are present in the stomach.'" This goal also is somewhat difficult to attain and the continued secretion of acid gastric juice during the night is even more difficult to control than Sippy appreciated. Nevertheless, the rationale of the program is valid and it will be presented with the modifications indicated as the most practical and satisfactory type of management.

Neutralization of the acid gastric juice is maintained by means of the acid combining power of food proteins and by the acid neutralizing capacity of various types of alkali. It is important to point out two facts: first, that all foods and liquids when ingested stimulate the secretion of gastric juice, water being one of the most effective, and second, that the slight quantitative differences in secretion induced by various foods as worked out by Pavlov, are not of much practical importance. Fats inhibit gastric emptying and secretion, but this factor is not as important in maintaining neutralization of the gastric content as is the acid combining property of protein food. Furthermore, neutralization of the acid seems to accelerate gastric emptying more than the presence of fat inhibits it. The milk and cream mixture is used for its neutralizing value and because the added nutritive value of the fat in the cream is important.

DIET.—The customary schedule consists of the administration of 90 cc. of equal parts of whole milk and 18 per cent cream hourly from 7 A. M. to 7 P. M. The caloric intake and the taste may be modified as desired by increasing the hourly milk and cream feeding, by adding malt or chocolate syrup or by substituting whole milk or even skim milk for the milk and cream. A gain in weight is usually desirable. Many patients state they are unable to take milk or milk and cream, but very, very few indeed are actually unable to do so.

Small additional feedings may be given with or substituted for the milk and cream beginning on the first day of treatment or begun a few days later. A good program is to begin with one feeding on the second or third day and add one every other day until six are being given. It is well but not absolutely necessary to restrict the foods for the first three feedings to the following:

Cream of Wheat, Farina, Boiled rice, soft cooked egg, cream or custard or cornstarch pudding, jello, ice cream.

Orange juice and other fruit juices may be given as desired and often help to relieve the initial distaste for milk and antacid

When four feeding are reached the following may be added

Toast, crackers creamed soups (strained) plain cake soft-cooked egg

The gradual increase in the additional feedings has a definite psychologic value in that it enables the patient to see progress from day to day and gives him something to which to look forward In some instances particularly in moderate obstruction the six feedings may be too much and a three feeding schedule may be maintained to advantage for several weeks provided the caloric intake is adequate Ordinarily the patient will be ready some time in the third week to begin the so called three meal program' the hourly schedule of which is as follows

8 00 Breakfast
8 30 Powder
9 00 Milk and cream
9 30 Powder
10 00 Milk and cream
10 30 Powder
11 00 Milk and cream
11 30 Powder

12 00 Dinner
1 00 Powder
1 30 Powder
2 00 Milk and cream
2 30 Powder
3 00 Milk and cream
3 30 Powder
4 00 Milk and cream
4 30 Powder
5 00 Milk and cream
5 30 Powder

6 00 Supper
7 00 Powder
8 00 Powder
9 00 Powder
9 30 Aspirate stomach
Record amount and reaction

The following diet may be used

BREAKFAST

1 Serving of
Fruits
Orange juice
Peach puree
Applesauce
Baked apple (no skin)
Prune puree
Pear puree
Apricot puree

Cereals
Cream of Wheat
Oatmeal (well cooked)
Boiled rice

Egg (1 or 2)
Soft boiled
Soft poached
Scrambled with milk and butter

1 or 2 slices of toast and butter

1 cup of coffee
1 cup of tea
1 cup of Sanka
1 cup of chocolate

Cream and sugar as desired

DINNER

Soups (strained cream soup)
Rice
Pea
Potato
Celery
Spinach
Lettuce
Asparagus
String beans
Tomato
Carrots

1 Serving of
Baked potatoes
Mashed potatoes
Rice
Spaghetti
Macaroni
Noodles
White or whole wheat bread rolls or biscuits

Vegetables strained or pureed or cooked until soft
Carrots
Peas
Beets
Squash
Asparagus
Spinach
Green beans

Meat 1 small serving of
Roast chicken
Stewed chicken
Broiled whitefish
Scraped beef
Minced beef or diced beef with gravy
Small portions of roast
Lamb
Beef
Mutton
Broiled steak and lamb chops may be taken after two or three months if thoroughly masticated

Desserts

1 Serving of
Bavarian cream
Lemon sponge
Grape sponge
Blanc mange
Cornstarch pudding
Tapioca custard
Vanilla custard
Ice cream
Sponge cake
Angel cake
Lady fingers
Arrowroot cookies
Vanilla wafers
Plain cake
Jello with whipped cream
Caramel custard
Cheese

SUPPER

Cream soup (see noon list)
Rice *or*
Cream of Wheat *or*
Soft egg

Crackers o
Buttered toast

Desserts (see noon list)

The diet consists of a fairly generous breakfast with dinner at noon and a light supper not exceeding 400 or 500 cc in total bulk The average caloric and vitamin intake on the three-meal ulcer management program is adequate, but additional supplementary vitamins may be prescribed if desired The patient is expected to follow the program outlined for a year or more reporting to the office or clinic at approximately monthly intervals for such changes as may be needed for x ray examinations or for other subsequent studies as indicated

ANTACIDS —Alkalis of various types especially calcium carbonate have been used in the treatment of indigestion from time immemorial The standard Sippy powders for many years consisted of (*a*) sodium bicarbonate (2 0 Gm) combined with calcium carbonate in doses of 0 65 1 3 or 2 0 Gm and (*b*) heavy magnesium oxide (0 65 Gm) and sodium bicarbonate 0 65 Gm These powders have excellent neutralizing value The calcium and sodium bicarbonate powders are the basic ones administered the magnesia powders being substituted for them only as needed for the regulation of the bowels Some patients do not require any magnesia powders others require three four or more If too many are given diarrhea and abdominal cramps ensue if too few are taken fecal impactions in the rectum or sigmoid may result Various other alkalis may be used The soluble sodium bicarbonate is much more likely to produce alkalosis than are the less soluble salts such as calcium carbonate tribasic calcium phosphate magnesium trisilicate or aluminum hydroxide Preference should be given to calcium carbonate (2 0 Gm doses), tribasic calcium phosphate (4 0 Gm doses) and magnesium oxide (0 5 or 1 0 Gm doses) Aluminum hydroxide must be used in rather large amounts (30 cc doses) if satisfactory neutralization is to be maintained

The alkali should be given hourly from 7 30 A M to 7 30 P M and at 8 00 8 30 and 9 00 P M If desired it may be combined with the milk and cream at hourly intervals It is not sufficient to prescribe one to two doses after each meal The hourly dose required varies with the preparation used The effectiveness of the amount used in each case may be checked by determining the degree of neutralization in the gastric content obtained in samples aspirated at various times during the day A good routine procedure is a daily aspiration at 9 30 P M and a sampling at 4 00 P M., three to four times a week Considerable difference of opinion exists with regard to the hydrogen ion concentration optimum for the healing of ulcer, for many lesions heal in the presence of acid gastric content There is evidence however that the best conditions obtain when the pH is above 4 0

ASPIRATION OF THE STOMACH —The routine gastric aspiration at bedtime is important because the emptying of the stomach decreases the period during which the ulcer is exposed to the action of the acid gastric content When the aspiration is performed approximately thirty minutes after the taking of a powder the aspirate should contain no free acid if the dose of alkali is adequate If the stomach empties rapidly however the powder may be discharged into the duodenum in a few minutes and the stomach then secretes the 20 to 40 cc of clear and highly acid gastric juice subsequently aspirated The aspiration also has the psychologic effect of reminding the patient that the evening meal should be small and that his definite regimen should be carefully followed The patients as a rule quickly become accustomed to the procedure learn the technic and are able to continue the aspirations for months if necessary until the quantity obtained regularly does not exceed 50 to 100 cc As a rule aspiration is not so important in gastric ulcer or in nonstenosing duodenal ulcer as it is in pyloric or duodenal lesions with marked narrowing of the channel but occasionally nonobstructive lesions are associated with retention due presumably to pylorospasm hypertrophic stenosis of the pylorus or to some disturbance in the reflex opening mechanism

CONTROL OF THE NIGHT SECRETION —In patients with gastric and more especially in those with duodenal ulcer the stomach usually continues to secrete rather large quantities of highly acid gastric juice for the first few hours during the night a fasting so called night secretion definitely greater than the fasting secretion of the otherwise normal stomach It is not due to the milk and cream and alkali administered during

the day for it occurs without such a program This excessive continued night secretion constitutes a hindrance to healing occasionally prevents healing and is difficult to control The administration of 0.5 to 1 0 mg of atropine sulfate by mouth at 6 00 P M and again after the evening aspiration is helpful Rather rarely additional doses (2 0–4 0 Gm) of calcium carbonate at 10 00 P M midnight 2 00 A M 4 00 A M and 6 00 A M may be in order In very rare cases the milk and cream schedule may be continued through the night or a continuous drip therapy be used

CONTINUOUS DRIP THERAPY —The administration of food or antacid or both by means of a continuous drip through a nasal catheter has certain advantages as well as disadvantages The feeding is in effect a fistula feeding thus eliminating the very important cephalic phase of gastric secretion The Winkelstein formula consists of 1 liter of milk containing 5 Gm of sodium bicarbonate every eight hours Very satisfactory neutralization can be maintained throughout the day and night It is as a rule not feasible to continue this procedure for more than a week or two after which a careful program should be followed The disadvantage consists chiefly in the discomfort induced by the presence of the nasal catheter the difficulty of adjusting the drip properly the dryness of the throat and the possible greater frequency of pulmonary complications

Complications of Antacid Therapy—ALKALOSIS —The term "alkalosis is applied to an alteration of the electrolytes of the blood serum characterized by an elevation of the carbon dioxide content and the pH It may be produced by the administration of soluble alkali (sodium bicarbonate) in which case there is also an elevation of the fixed base (sodium) in the serum or by depletion of chloride (low intake of salt vomiting aspiration of the stomach) in which case the fixed base of the serum is not elevated but is in fact lowered Since sodium bicarbonate is no longer prescribed as an antacid the first type of alkalosis is seen almost exclusively in individuals who have acquired the baking soda habit The second type is seen in patients with continued vomiting from obstruction at the outlet of the stomach both benign and malignant and in patients receiving (*a*) a low intake of chloride and (*b*) routine nocturnal aspirations of the stomach

In both of these types of alkalosis the kidney is not primarily involved even though there is a rise in the blood urea nitrogen and a decrease in renal function The initial symptoms of alkalosis consist of loss of appetite with distaste for the milk and cream and powders Nausea and vomiting may ensue Weakness and lassitude may be marked often accompanied by a dull headache and slight clouding of the sensorium Tetany is rarely seen Moderate chemical alkalosis is frequently present without symptoms

TREATMENT consists of the discontinuance of soluble alkali if this is being given and of the administration orally or parenterally of large amounts of fluid and sodium chloride —3000 to 4000 cc of normal saline daily by hypodermoclysis or intravenously or an equivalent amount by mouth An additional 5 to 10 Gm of sodium chloride may be given orally in the form of pills or capsules As a prophylactic procedure 3 to 5 Gm of sodium chloride may be added to the daily ration of milk and cream

BOWEL DISTRESS —Abdominal distress during ulcer management is usually attributable to a functional disturbance resulting from improper regulation of the bowels The powders and the diet should be manipulated in such a fashion as to produce daily formed stools

FECAL IMPACTIONS —Special attention must be given to regulations of the bowels to prevent the formation of rectal or sigmoidal impactions of feces This is best accomplished by alternating the calcium and magnesium powders until a mild diarrhea is produced and then determining just how many magnesium powders are required to maintain normal bowel function When impactions form they must be broken up digitally at once and removed manually or with large enemas At times the rectum is found filled with soft putty like material which the patient is unable to expel The enemas and rectal examinations should be continued until the rectum is proved to be empty In rare instances a large calcium stool may lodge in the sigmoid and the clinical picture

of paralytic ileus develops Watchful waiting with the application of hot stupes or an electric pad to the abdomen and if necessary the use of a Wangensteen or Miller Abbott tube for the relief of the nausea vomiting and distention, is rewarded in a day or two by the passage of the stool into the rectum at which time it can be removed manually Warm oil retention enemas may be helpful but repeated large water or soapsuds enemas are likely to produce further distention of the abdomen without bringing the fecal mass down into the rectum

RENAL AND URETERAL CALCULI —There is no satisfactory statistical proof that this complication is seen in greater than the normal frequency in patients receiving antacid therapy Theoretically and practically there seems to be no contraindication to the use of the nonabsorbable salts of calcium magnesium and aluminum

ACUTE APPENDICITIS —This complication of antacid therapy is seen so frequently that the possibility must always be considered although statistical evidence that it occurs in greater than the anticipated frequency does not exist

Inhibitory Drugs —ATROPINE and SIMILAR DRUGS are commonly used in the treatment of ulcer presumably as antispasmodics but it is difficult to prove that they lessen pylorospasm or spasm at the site of the ulcer They do inhibit to a certain extent however both gastric peristalsis and gastric secretion and make possible neutralization of gastric acidity with smaller amounts of alkali than would be needed without them Atropine is as satisfactory as any of the antispasmodics The maximum total daily dose tolerated is usually 1 0 to 1.5 mg and does not exceed 2 0 or 3 0 mg dryness of the mouth blurring of vision and toxic psychosis being not uncommon with large daily doses (3 0 mg or more) Since the evening and night secretions are the most difficult to control the atropine is used most effectively perhaps if given in the afternoon at 4 or 6 P M and at bedtime

X-ray Therapy —Radiation therapy is helpful in certain cases not as a stimulant to the healing of the ulcer for there is no evidence that the x ray ever directly stimulates the process of tissue repair but as a means of inhibiting gastric secretion and thus facilitating healing The radiation should be directed at the fundus of the stomach The effect on secretion is variable and as a rule not permanent If a phase of complete achlorhydria is produced partial or complete healing invariably occurs, the degree depending apparently on the reparative ability of the tissue and the duration of the achlorhydria

Hormone Therapy —Enterogastrone a hormone prepared from duodenal mucosa and certain extracts of pregnancy urine normal female urine and male urine exert a definite inhibitory effect upon gastric secretion but these substances are not yet available in sufficient quantity for extensive clinical trial

Foreign Protein Therapy —Foreign protein therapy has no rational basis in the treatment of ulcer except the psychotherapeutic as illustrated by the excellent results ' obtained by the intravenous injection of distilled water

Foci of Infection —These should be removed for local reasons a remission of symptoms may follow their removal but there is no evidence that the relationship is causal

Complications — *Perforations* — ACUTE PERFORATION —Acute perforation is the most dangerous complication of peptic ulcer and accounts for 65 to 85 per cent of the deaths from this disease The duodenum is the site of the perforation nine times more frequently than the stomach The accident occurs forty nine times more often in males than in females An ' ulcer history is present in from 60 to 75 per cent of the cases

DESCRIPTION —Moynihan s description of the clinical picture is superb The picture is so characteristic that error is hardly possible I have had the opportunity of seeing three patients within five minutes of this terrible catastrophe and so deep an impression was made upon me that the recollection is a haunting one For the agony suffered by the patient is almost beyond belief and is written on every line of a face that speaks of torture The face is pale haggard anxious and appealing the eyes wide and watchful the brow and temples bathed in sweat the hair soaked The patient struggles for breath in short panting respirations which are wholly costal for the diaphragm

being an abdominal muscle is fixed Words spoken are jerked out in expiration only every syllable is part of a deep moan What strikes every onlooker is that the patient s body is rigid and motionless no slightest movement dare be attempted If an en deavor is made to touch the abdomen the patient s hands are at once lifted in protest and in protection but the chest and abdo men stay motionless When examination is made it is realized at once that the patient is cold and the temperature will rarely be found more than 95° or 96° F The abdomen is immobile and the muscles are taut and rigid hard as a board it is said but if there is anything harder it is the abdomen in this time of catastrophe A further examination of the abdomen will almost always show an area of greater tenderness and if possible of added rigidity over the area involved in stomach or duodenum

When the pulse is examined a great sur prise is felt for it is not increased in fre quency nor diminished in volume blood pressure is not diminished and in a few cases that we have examined the blood volume is unchanged There is therefore no shock Great harm has come from the almost in variable use of the word shock to describe the conditions The use is really inde fensible and indeed dangerous When a pa tient is seen whose general and local condi tions suggest the occurrence of a catas trophe and the pulse is found to be normal the practitioner is betrayed for he has learnt that among the symptoms of rupture is shock' and shock being absent the diag nosis is impugned or denied Shock is never a symptom of perforation It is a symptom of peritonitis which follows quickly upon leakage from the stomach or duodenum In the patient s interest no less than in the service of truth we must discharge the word shock from its use in this connection

The period of initial profound prostra tion varies in different patients and may be ascribed to variations in the size of the per foration the character of escaping contents —especially in respect to acidity—the gen eral condition of the patient and so forth Within an hour or two it is followed by a period of reaction characterized by an improvement in the appearance of the pa tient pallor being replaced by flushing lines of anxiety being smoothed away, and the body growing warmer But the pulse stead ily rises the rigid abdomen becomes fuller and since the diaphragm is being pushed higher respirations become shallower For reasons which I gave many years ago fluids leaking from the stomach tend to trickle down to the right iliac fossa and to over flow into the pelvis So there may be acute pain or tenderness in the right iliac fossa and a careless diagnosis of appendicitis may be made It is in this stage that the absence of liver dullness upon which so high a value has long been placed will be recognized It is almost valueless I very rarely percuss the abdomen and I have been amused to see the liver percussed when it could be felt! At this time too vomiting may first be no- ticed and from now onwards conditions suf fer a fast and progressive deterioration

It is however the earliest stages of per foration for which we should be on the alert And remembering what has been said we may conclude that perforation of an ulcer in the stomach or duodenum is almost invari ably preceded by the history of a chronic ulcer and that some exacerbation of symp toms may have been observed in a few pre- ceding days When perforation occurs the patient is struck motionless he endures a degree of agony that reaches the very limit of human power to withstand his face is sweating he pants and groans on expira tion as he tries to speak His abdomen is inflexibly and unalterably rigid His pulse is normal No more need be said These signs and symptoms are compulsion enough for any medical man to say that Here is a grave abdominal catastrophe that cannot be treated except by surgery and to enlist the earliest possible help of the surgeon

If operation is not performed generalized peritonitis usually ensues the abdomen loses its boardlike character but not its rigidity or tenderness it becomes distended the pulse becomes gradually rapid weak feeble the respirations become more rapid and shal low Hippocratic facies appear and the pa tient dies the typical peritonitic death in the course of two to five days

Differential Diagnosis —The differen tial diagnosis of acute perforation is rarely difficult Biliary renal and intestinal colic lack the boardlike rigidity Perforation of

the gallbladder, however, is usually indistinguishable from that of the stomach or duodenum except for the fact that it typically occurs during or after the apparent subsidence of an attack of acute cholecystitis In coronary thrombosis not only is the rigidity absent but usually there is some radiation of the pain to the precordium sternum neck or arms In lobar pneumonia the temperature is elevated the respiratory rate is increased and the normal pulse to respiration ratio of 4 to 1 is decreased to 3 or 2 to 1 In the gastric crisis of tabes dorsalis the abdominal rigidity is absent Argyll Robertson pupils are usually present The onset of acute appendicitis is less sudden the rigidity is less intense the tenderness is most marked over McBurney s point In mesenteric occlusion and intestinal obstruction the pain is rhythmical intermittent and the rigidity less intense In ruptured ectopic pregnancy the pain and tenderness are in the lower abdomen and the rigidity is only moderate

The most difficult differentiation is that of acute pancreatitis If the patient is a female the diagnosis of acute pancreatitis is much more probable because 98 per cent of acute perforations in peptic ulcer occur in the male Disease of the biliary tract is usually present in acute pancreatitis but there may be no history of biliary colic Marked shock is almost always present The abdominal rigidity is not so intense or widespread nor the tenderness so complete Jaundice of slight degree is present in about one half the cases and often at an early stage the patient develops a characteristic slate blue tinge of color seen most distinctly in the lips in the lobes of the ears in the face and in the fingernails The urinary diastase the fasting blood sugar and the glucose tolerance curves are elevated in some cases Extreme gaseous distention of the stomach and colon (meteorism) may be observed

TREATMENT —The urgent and immediate indication in acute perforation is immediate operation Spontaneous closure does occur but operation should never be deferred in the hope that it may take place The earlier the operation the better the prognosis for few die if the operation is carried out within ten or twelve hours Rarely when the patient is first seen several hours after the onset of symptoms and from the rapid subsidence of the pain the sharp localization of the tenderness and rigidity and the excellent condition of the patient it is apparent that spontaneous closure has already occurred surgery may be deferred and the patient treated by starvation for two or three days before instituting ulcer management In the vast majority of cases however operation should be performed at once The perforation should be closed by suture and no further procedure carried out unless it is evident that the suturing has produced marked stenosis in which case a gastroenterostomy should also be performed Some surgeons prefer to carry out an initial primary subtotal gastrectomy but the mortality rate is higher

In *subacute perforation* the clinical picture is similar but less intense Spontaneous closure of the defect may occur as a result of fibrinous adhesions to omentum liver pancreas or other structure and recovery ensue without surgical interference These so called formes frustes perforations are more frequent than is generally recognized but this fact does not justify failure to operate when acute perforation is diagnosed or suspected In some cases of perforation, even though spontaneous closure takes place abscesses develop about the ulcer or the infection extends to form a subphrenic abscess

In *chronic perforation* the base of the ulcer is usually formed by the capsule of the pancreas or liver rarely is the parenchyma of these organs attacked Chronic perforation is of very little clinical significance except when a gastrojejunocolic fistula is produced

In *peptic ulcer of the esophagus* perforation of an acute subacute or chronic type may take place into the mediastinum pleura or pericardium

Massive Hemorrhage — DEFINITION — Massive hemorrhage may be defined as the vomiting of gross blood or the passage of tarry stools The bleeding may be of all grades of severity from the 60 cc required to give a tarry stool without symptoms to several hundred cc resulting in severe collapse and even rapid death

MORBID ANATOMY —Fatal hemorrhage is almost invariably arterial in origin the pan

creaticoduodenal the gastric coronary or one of their main branches being eroded

INCIDENCE.—Probably 20 to 25 per cent of all patients with peptic ulcer experience massive bleeding at some time or other

The MORTALITY RATE varies from 1.5 to 20 per cent or higher It rises with age, being at least four times higher in patients over fifty than it is in patients under fifty It does not rise materially with recurring hemorrhages

MELENA NEONATORUM or hemorrhage in the newborn deserves separate mention for in about 50 per cent of the cases it is due to peptic ulcer The symptoms appear on the first day of life never later than the fifth day and the deaths all occur within the first two weeks (Hurst Theile)

SYMPTOMS AND DIAGNOSIS.—Since peptic ulcer is the most frequent source of hemorrhage in the digestive tract it should be suspected in every case regardless of the presence or absence of pain In gastric ulcer hematemesis is usually present as well as melena in duodenal ulcer it occurs in about one fourth of the cases The patients usually give a history of epigastric distress of the ulcer type but there may be no distress whatsoever at the time of hemorrhage or indeed previously

The symptoms consist of faintness weakness dizziness headache perspiration thirst dyspnea syncope and collapse the severity depending largely upon the suddenness and severity of hemorrhage and the resultant rapid drop in blood pressure Usually the vasomotor system regains its tone rapidly and the blood pressure rises but in severe hemorrhage it remains low usually below 100 often 90 mg of mercury the pulse more or less gradually increases in rate and the patient continues in shock The more marked and persistent the drop in the blood pressure and the more rapid and weak the pulse the greater is the danger In the first few hours the blood count may be normal except for the moderate leukocytosis of hemorrhage The drop in the red cell count and in the hemoglobin appears later as the total blood volume is restored by dilution A moderate azotemia occurs due to the absorption of protein from the blood in the intestine the dehydration and to decreased renal function as a consequence of the drop in the blood pressure with the resultant diminished blood flow through the kidney

PROGNOSIS.—Recovery is the rule but death may occur at any time usually two to five days after the onset of symptoms and results either from exsanguination or from intercurrent complications such as pneumonia or perforation

TREATMENT.—The time honored therapy in massive hemorrhage is bed rest elevation of the foot of the bed application of an ice bag to the epigastrium morphine in doses adequate to quiet the restlessness and complete starvation for several days In recent years the frequent feeding program of Meulengracht has again called into question the wisdom of starvation The following program based essentially on that used and recommended by Sippy has been found superior to routine starvation and is thought to be at least equal to the Meulengracht procedure

Absolute rest in bed should be maintained and restlessness controlled by the use of *morphine* 1/8 1/6 or even 1/4 of a grain every four hours combined with *atropine* sulfate 1/120 1/100 or 1/75 of a grain The patient should not be snowed under The blood pressure and the pulse rate should be watched carefully readings being taken at hourly or half hourly intervals The blood count does not usually drop until several hours after the initial hemorrhage and hence is not as good an index of the severity of the bleeding as are the blood pressure and the pulse rate

Blood transfusion is indicated when the pulse rate exceeds 120 per minute and the blood pressure drops below 90 or even 100 mm of mercury When the bleeding takes place slowly and continuously the pulse rate and blood pressure may not reach these levels and yet transfusion may be indicated because of the anemia If the erythrocyte count is below 3 000 000 cells per cubic millimeter transfusion is desirable if it is below 2 000 000 cells transfusion is imperative Many patients recover spontaneously from such levels but their margin of safety is very narrow and a relatively small hemorrhage may prove fatal The blood should be matched most meticulously Each transfusion should consist of 500 or 600 cc of whole blood and as many should be given as

necessary The greater the number of transfusions required the graver the prognosis, not because the transfusions are harmful but because the great need for them constitutes evidence that a large and probably sclerotic vessel is the source of the bleeding

Starvation is indicated only if the patient is vomiting in which case it should be continued until this has subsided and the patient desires food Dryness of the mouth may be relieved by cracked ice and by the daily subcutaneous (*not* intravenous) administration of small amounts (1000–1500 cc) of normal saline with or without glucose Occasionally, if the lesion, from previous x ray examinations, is known to be duodenal and accompanied by considerable stenosis, starvation may be combined with continuous aspiration of the stomach through a Wangensteen tube A surprising amount of highly acid gastric juice may be obtained If the bleeding ceases promptly the procedure may be continued

Feeding and antacid ulcer management is in the absence of vomiting preferable to starvation Milk and cream in equal parts or whole milk may be given in amounts varying from 30 to 120 cc usually 90 cc hourly from 7 00 A M to 10 00 P M and at two hour intervals through the night Calcium carbonate, 2 0 Gm should be given hourly from 7 30 A M to 9 30 P M or on the hour with the milk and during the night with the milk in 4 0 Gm doses wakening the patient if necessary A sufficient number of powders of magnesium carbonate in doses of 2 Gm, usually totaling 2 to 10 Gm daily, must be substituted for the calcium carbonate to *prevent rectal impactions*

This program is continued until the stools have been negative for occult blood by the benzidine test for at least two or three days and until the patient s general condition is good at which time roentgenologic and gastroscopic examinations are in order to determine the location nature and extent of the lesion and the complications present Aspiration of the stomach may then be carried out safely If the occult blood in the stool does not disappear in the course of two or three weeks and if the patient is in good condition, the x ray examination should not be further deferred The risk of the procedure, if carefully carried out, is small, and it may be found that the bleeding lesion is not a benign ulcer, but a frank neoplasm or varices of the esophagus

Surgical treatment may be indicated in certain cases Usually by the time the need for ligation of the artery has become apparent the patient has become a poor operative risk and hence surgical intervention is further deferred It may be difficult to find the bleeding vessel at operation and to deal with it adequately if found There is evidence that immediate surgical treatment employed routinely in all cases of hematemesis and melena would increase rather than lower the mortality rate On the other hand it may be possible to select the patients with rapid continued bleeding and to lower the mortality rate in these cases by surgical treatment Gastro enterostomy alone is not effective The bleeding vessel must be ligated Subtotal gastrectomy may be advisable In patients with recurring massive hemorrhage subtotal gastrectomy may be indicated after recovery as a prophylactic against further bleeding although ulcer and massive hemorrhage do recur after this type of therapy as well as after other forms of medical and surgical treatment Nevertheless the incidence is low and hence subtotal gastrectomy may in certain cases be chosen as the best procedure

Acute Perforation and Massive Hemorrhage—These are as a rule independent complications of peptic ulcer About 10 per cent of the acute perforations occur in patients who have experienced massive hemorrhage Occasionally the two complications occur within a few days of each other After recovery the ulcer may recur and either complication ensue

Obstruction—DEFINITION—The term obstruction" referring to obstruction to the passage of food from the stomach *to the* intestine is loosely used It is often applied to persistent vomiting or the vomiting of food eaten the previous day or the *failure* of the stomach to empty properly as evidenced by abnormal gastric retention *of a* food or barium meal The terms 'obstruction' and 'retention are thus *confused* they are not synonymous Retention may be present in the absence of *gastric disease* Obstruction *per se* may be due to spasm of

the pylorus to edema and inflammatory swelling about a pyloric or duodenal ulcer, to cicatricial stenosis, or to a combination of these factors The criteria of obstruction must therefore be critically evaluated to determine their significance

DIAGNOSIS —The mere retention of food or barium in the stomach for abnormal periods is not direct evidence of obstruction unless the retention be extreme If food is retained in the stomach for twenty four hours as may be demonstrated by the vomiting of food taken the day previously, obstruction is almost always present The presence of sarcinae and yeast in the gastric content betokens continued retention for many days or weeks and thus constitutes definite evidence of obstruction

X RAY affords on the whole the most valuable evidence of obstruction for it permits determination of the site of the lesion and usually of its nature and also discloses the site of the obstruction its nature and the degree of stenosis Pylorospasm although it may occur with an ulcer at any point in the stomach or duodenum is usually not very important unless the lesion is intrapyloric If the pyloric obstruction is due to a hypertrophic stenosis of the pylorus surgical relief will frequently be required Usually however the lesion is duodenal in location and the question to be answered is the degree of cicatricial stenosis present Often this cannot be settled until the initial spasm edema and inflammatory swelling have subsided after a few days or even a few weeks of treatment The lumen of the normal duodenal bulb has a diameter of 2 to 3 cm If this is decreased to 5 or 10 mm the stenosis is moderate if decreased to 2 to 4 mm the stenosis is marked and if the lumen is decreased to a hair line or to a diameter of 1 mm the stenosis is high grade usually accompanied by gastric dilatation ballooning of the antrum and hyperperistalsis The maximum width of the channel should be determined fluoroscopically not from the film for the film may be exposed at the moment the muscle is in contraction thus suggesting a much more marked stenosis than is actually present

TREATMENT —Obstruction is the most frequent *indication for surgical treatment* in peptic ulcer The term is a relative one as has been pointed out previously, and hence the indication is relative In general it is wise to try the effect of medical management for ten or fourteen days before arriving at a decision for Sippy s original estimate that in 85 per cent of the cases the obstruction is due to spasm or inflammation is approximately correct In general need for *surgical intervention* may be said to be definite when two or more of the following conditions are present continued vomiting before admission to the hospital, motor meal retention sarcinae or yeast in the gastric content a quantity of 800 to 2000 cc obtained at the bedtime aspiration rapid loss of weight on management gross peristaltic waves passing across the contour of the stomach from left to right and the x ray disclosure of a huge dilated stomach with hyperperistalsis but with little or no barium passing into the duodenum When the evening aspiration is only 300 or 400 cc and if the patient does not lose weight but even gains weight on treatment the indication for operation is much less definite

The *location* and the *nature of the obstruction* are important considerations In the case of the duodenal ulcer operation is definitely not indicated for obstruction if the maximum lumen through the deformity as seen roentgenologically is over 5 mm in diameter usually not if the lumen is over 2 or 3 mm in diameter and on the other hand usually is indicated if the maximum lumen is less than 2 mm in diameter The width of the channel usually persists relatively unchanged as the ulcer heals occasionally it increases rarely does it decrease In the case of intrapyloric or prepyloric ulcer the obstruction and retention may decrease rapidly under management or it may persist The retention occasionally seen with ulcers of the lesser curvature of the stomach and due presumably to pylorospasm disturbance of the neuromuscular reflex or associated hypertrophic stenosis of the pylorus may be very persistent and warrant surgical interference

Depending upon the surgeon and the conditions present the *operations of choice* for obstruction are posterior gastro enterostomy pyloroplasty and gastroduodenostomy although some surgeons prefer a primary subtotal gastrectomy The initial ulcers almost

invariably heal following operation the difficulty is to be found in their recurrence later, or rather in the development of new ulcers later at the new stoma or in the stomach Statistics on the *incidence of recurrent ulceration* vary roughly from 2 to 40 per cent Subtotal gastrectomy seems to result in a lower incidence of recurrence, although the initial mortality rate is higher A further disadvantage of subtotal gastrectomy is the fact that the jejunal ulcers which do occasionally develop after this operation are extremely difficult to treat medically and can be treated surgically only by further resection and at greater risk

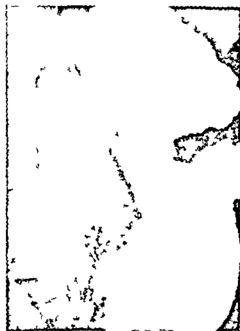

Fig 70—Hour glass contracture of the stomach secondary to gastric ulcer the ulcer being visible *en face* In this case the contracture was chiefly spastic for it disappeared almost completely as the ulcer healed The patient Unit No 130044 a female fifty two years of age had had intermittent epigastric distress for ten or twelve years Maximum free acidity 130 (histamine) The ulcer was repeatedly seen roentgenologically as its course to complete healing was followed but repeated gastroscopic examinations failed to disclose its presence, due presumably to the fact that it was located in a so-called gastroscopic blind area

Hour glass contracture of the stomach usually results from long standing chronic gastric ulcer although a type of hour glass deformity is seen in certain cases of carcinoma lues and diaphragmatic herniation It is a strange fact that hour glass contracture is eight or nine times more frequent in females than it is in males The ulcer is found healed at autopsy in about half the cases The incisura is sharp and narrow, involving the greater curvature almost exclusively and drawing it toward a point on the lesser curvature at which there may or may not be seen a penetrating ulcer of variable size usually rather small (see Fig 70) A bilocular or rarely a trilocular stomach results, seen much more clearly when the stomach is distended than when it is contracted. Rarely is the stenosis sufficient to be actually obstructive The contracture may involve the mucosa chiefly and hence not be apparent from the serosal surface

The history is as a rule, of many years duration the distress is mild vomiting massive hemorrhage or acute perforation may occur Not infrequently these patients give a history of a massive hemorrhage or an acute perforation in the second or third decade of life followed by many years of chronic indigestion Medical treatment usually suffices although occasionally the ulcer recurs with sufficient persistence or the obstruction is sufficiently complete to warrant operation

Jejunal Ulcer—With the exception of the uncommon ulcer of Meckel s diverticulum and the very rare primary ulcer of the jejunum associated with ectopic gastric mucosa peptic jejunal ulcer is a complication of gastro enterostomy

Incidence—Statistics vary greatly as to the incidence of the lesion some authors reporting it to be as low as 1 or 2 per cent, while others find it as high as 40 per cent. The latter figure is more nearly correct Ulcer develops in a certain number of cases irrespective of the type of gastro enterostomy performed irrespective of the type of anastomosis made and irrespective of the suture material used The lesion is said to be more frequent when an entero enterostomy is made in addition to the gastro enterostomy and is particularly frequent if a Roux Y operation is performed These clinical observations are in accord with the experimental studies mentioned in the section on etiology and pathogenesis Jejunal ulcer is definitely less frequent after subtotal gastrectomy than it is after gastro enterostomy alone and it is less frequent when the procedure is carried out for gas

the ulcer than it is when carried out for duodenal ulcer Jejunal ulcer practically never follows gastro enterostomy for gastric carcinoma

SYMPTOMS —The symptoms of recurrent jejunal ulcer resemble those of primary gastric or duodenal ulcer although the relationship of the distress to food taking is likely to be less definite and the pain usually is referred to the left mid abdomen or even to the left lower quadrant Massive hemorrhage occurs quite frequently Acute perforation is rare Chronic perforation is common particularly into the colon producing even without pain a gastrojejunocolic fistula and severe diarrhea

DIAGNOSIS —Recurrent abdominal distress in a patient with a gastro-enterostomy always suggests the presence of jejunal ulcer Usually the lesion can be demonstrated roentgenologically not infrequently it can be seen gastroscopically also

TREATMENT —Medical treatment is difficult If it is undertaken the course of the lesion should be followed closely by x ray and gastroscopy Surgical treatment is usually to be preferred and in the case of gastrojejunocolic fistula is imperative The gastro enterostomy may be simply undone provided the channel through the bulb is adequate A new duodenal ulcer may then develop If a second gastro-enterostomy is made at the time the first one is undone a new jejunal ulcer is likely to develop If subtotal gastrectomy is performed the mortality rate is somewhat higher than it is for primary resection and there is a fair likelihood of recurrence after resection for these are the so-called intractable cases of ulcer The treatment of jejunal ulcers developing after resection is most difficult Surgically the only available procedure is further resection Medically any or all measures may be tried complete healing may take place but recurrence is the rule It is important to know that in the intractable cases recurrences occur after both medical and surgical treatment Extreme care patience and perseverance must be maintained for many years It is perhaps in this group that intensive radiation therapy is most helpful

DISEASES OF THE INTESTINES

DISEASES OF THE DUODENUM

Peptic ulcer is the most frequent affection of the duodenum It usually appears in the first portion the so called duodenal bulb, it occurs rather often at the junction of the first and second portions occasionally it develops in the upper part of the second portion of the duodenum and rarely as far down as the ampulla of Vater Lesions occurring beyond this point are not simple peptic ulcers (See Peptic Ulcer)

Duodenitis is a term applied to a non specific inflammation usually seen anatomically as a part of the erosive gastritis of Konjetzny a gastroduodenitis Clinically the diagnosis of duodenitis is made at times in patients who give a history of epigastric distress of the ulcer type and in whom the

roentgenologist finds a duodenal cap which fills and empties rapidly, seems 'irritable' and rather fuzzy in outline, but without definite deformity or crater formation Not infrequently in such individuals an ulcer crater or deformity is found months or years later It is probable that the process represents an early phase of the acid attack on the mucosa and that the basic problem therefore is that of peptic ulcer (See Peptic Ulcer)

Diverticula of the duodenum may be divided into those occurring in the bulb and those in the remainder of the duodenum The former are invariably secondary to peptic ulcer and do not cause symptoms Diverticula of the second, third and fourth portions are usually considered as congenital but the mechanism of their formation is not known they are usually found accidentally by x ray and bear no relationship to the symptomatology present unless as occurs very rarely they become the site of infection and inflammation

Carcinoma of the first portion of the duodenum is a great rarity scarcely more than a dozen cases having been reported in the medical literature of the world In the other portions of the duodenum however the lesion is not uncommon (See Intestinal Neoplasms)

Stricture of the duodenum may occur at any level most frequently in the first portion as a result of peptic ulcer Congenital strictures usually involve the second portion are often complete and cause the death of the infant within a short time unless recognized and treated surgically Extremely rare cases have been reported of incomplete congenital stricture discovered in adult life and producing intermittent attacks of nausea and vomiting Duodenal obstruction may be produced also by external adhesions such as those resulting from an adhesive tuberculous peritonitis severe cholecystitis, or neoplasm of the biliary tract

Duodenal stasis is a term applied to cases in which considerable to and fro churning or 'puddling of barium with reverse peristalsis is seen roentgenologically in the second portion of the duodenum It is a normal variant found most typically in lean lanky individuals with long abdomens It has been interpreted erroneously as a cause of symptoms diets belts and operations have been devised for it

Mesenteric duodenal ileus is a rare condition in which the third portion of the duodenum caught between the spine posteriorly and the mesenteric vessels anteriorly becomes partially or completely obstructed The duodenum is enormously dilated The symptoms are those of high intestinal obstruction with continued upper abdominal distress, nausea and vomiting and loss of weight

VISCEROPTOSIS

(Splanchnoptosis Glenard s Disease)

This is a term applied to prolapse or falling of the various viscera It is not a disease entity but rather a manifestation of a lean lank body build with more or less relaxation of the abdominal wall The stomach and transverse colon may extend down to the brim of the pelvis Various symptoms have been ascribed to the condition belts have been devised for it as in duodenal stasis and operations even have been performed in attempts to elevate the various structures As a matter of fact there are only *two* organs which are ever affected seriously by ptosis (1) the kidney with resulting attacks of Dietl s crisis and (2) very rarely indeed the spleen which has been known to be-

come strangulated in the pelvis Otherwise visceroptosis may be disregarded

WALTER L PALMER

DIARRHEA

Definition —Diarrhea consists in the evacuation of watery or unformed stools It may be acute or chronic It is a symptom present in a great variety of disorders and diseases hence all cases should be studied carefully

Etiology —The numerous causes of diarrhea may be partially classified and listed as follows

- Enteric infections such as bacillary dysentery cholera, typhoid and paratyphoid fevers, food poisonings (usually staphylococcal) and parasites particularly *E histolytica*
- Food sensitizations particularly shell fish strawberries and eggs
- Poisons such as arsenic, mercury silver salts
- Avitaminoses particularly pellagra and sprue
- Toxic or septic states such as sepsis measles thyrotoxicosis Addison s disease chronic nephritis
- Circulatory disturbances secondary to cardiac decompensation or cirrhosis of the liver
- Emotional disturbances such as fear and grief
- Incomplete intestinal obstruction
- Non-specific infections such as regional enteritis and chronic ulcerative colitis
- Neoplasms of any type of the stomach pancreas or intestines

Symptoms —The clinical pictures seen in these different states vary a great deal particularly in severity and in duration but nausea and vomiting abdominal cramps tenesmus and frequent watery stools more or less characterize them all In the usual so called simple acute diarrhea the etiology is often not known and not discovered The attack lasts one to three days the stools vary from three or four to fifteen or twenty per day usually watery light brown or gray or green in color flaked with mucus and often with a very foul odor Blood is rarely present The intermittent cramps subside after the first day as does the vomiting The temperature is usually not elevated although it may rise 1 or 2° F rarely higher The leukocyte count is normal or slightly elevated In severe cases the prostration and collapse may be profound

Diagnosis —In simple acute diarrhea the diagnosis is made by the brief duration of the attack and by the failure to find a specific cause

Treatment.—In simple acute diarrhea, as in all diarrheas rest is of great importance It is well to keep the patient in bed and to give no food for the first twenty four hours Normal saline with 5 per cent glucose may be given if convenient subcutaneously or intravenously in amounts of 1000 to 1500 cc once or twice or even three times in twenty four hours depending on the degree of dehydration Hot water weak tea broth or barley gruel may be permitted in small amounts after the nausea and vomiting have subsided and if the patient has developed a real desire for food Boiled milk toast soft cooked eggs and custard may be given later Hot stupes may be applied to the abdomen although usually a hot water bottle or an electric heating pad is sufficient Atropine should be given in full doses 1/120 to 1/60 of a grain (0 0005 to 0 001 Gm) every four to six hours hypodermically When the pain is severe codeine sulfate 1/2 to 1 grain (0 03 to 0 06 Gm) or morphine sulfate 1/8 to 1/4 grain (0 008 to 0 015 Gm) should also be given as needed Paregoric and bismuth are of relatively little value Calomel a time-honored remedy is best avoided as is castor oil The irritating substance is usually removed by the diarrhea in a short time However castor oil causes such a complete evacuation of the colon that it is frequently followed by a cessation of bowel movements for one or two days Enemas or irrigations are not indicated The patient should be advised to rest and to adhere to a bland diet until the bowel function has been normal for several days

CONSTIPATION

Definition —Constipation is defined as the passage of unduly hard and dry fecal material The consistency of the stool is more important than the frequency of defecation or the quantity expelled The average normal individual passes one well formed

stool of good caliber daily although people in the best of health may defecate only one, two or three times per week Patients have various notions about normal bowel function and constipation some expect a large watery stool after each meal the majority consider themselves constipated if more than twenty four hours elapses without a bowel movement Those who complain of constipation usually are not constipated in the sense of passing hard dry stools but rather in the sense of not passing the quantity of feces with the frequency they desire True constipation without abdominal distress is as a rule atonic whereas if abdominal pain or discomfort is present, the constipation is usually spastic or hypertonic

Normal Intestinal Motility—The motility of the normal digestive tract varies considerably The stomach empties in from two to seven hours Digestion in the small bowel takes place rapidly the time required for completion after food leaves the stomach not exceeding two to four hours The undigested residue enters the cecum in a liquid state The chief change occurring in the colon is the absorption of water Normally as the food residue traverses the colon its consistency increases so that a solid column is emptied into the pelvic colon from the descending colon The defecatory reflex is initiated by the presence of a fecal mass in the lower sigmoid and rectum

The rate of transit through the colon varies enormously usually requiring from one to three days but not infrequently requiring four or five days or longer If the progress is so rapid that the residue is evacuated before the proper amount of water has been absorbed the stool is unformed mushy or watery whereas if motility is slow too much water is absorbed and the stool is hard and dry Diarrhea is thus defined as the passage of unformed mushy or watery stools constipation as the passage of stools that are hard and dry The frequency of defecation is not of great significance perhaps the average individual expels one formed stool daily many normal persons have two or three formed stools daily and on the other hand occasional individuals habitually pass perfectly normal stools at intervals of two to seven days The moderate amounts of gas evolved in the colon are usually absorbed by the blood the quantity passed per rectum as flatus depends on the diet and on the rate the colon propels the gas along

Atonic Constipation—This relatively uncommon condition may be said to exist when without abdominal distress the fecal matter reaching the rectum is hard and dry Symptoms arise from difficulty in expelling the large hard stools Satisfactory bowel function can usually be obtained by including in the diet adequate amounts of the more laxative foods such as oatmeal for breakfast spinach and prunes daily two other vegetables and two fruits either cooked or raw fruit juices whole wheat bread honey and syrup Some cases are helped by one or two ounces of brewers yeast daily Mineral oil or other mechanical or chemical laxatives are usually not necessary but on the other hand in the absence of abdominal distress do little harm

WALTER L PALMER

IRRITABLE COLON

Definition—The most frequent cause of abdominal distress is disturbed intestinal motility primarily in the colon with more or less hyperirritability and hypersensitivity In various sections of the world different names are applied to the syndrome varying concepts are in vogue and multitudinous types of treatment are prescribed

None of the terms used to describe the functional bowel distress syndrome are entirely satisfactory Perhaps irritable colon" is the best for the bowel is irritable' as evidenced by the distress and by the abnormality of the stool Similarly descriptive are the terms unhappy and unstable colon Spastic or hypertonic constipation is usually only partially correct for the constipation" thought by the patient to be present is frequently absent Chronic functional colitis is a contradiction of terms for itis means inflammation and inflammation is scarcely functional' Cathartic colitis is perhaps applicable in cases with a cathartic habit Spastic colitis emphasizes the element of spasm rather than that of disordered function Mucous colitis is applied to those cases in which large amounts of mucus are expelled particularly the so called mucus

casts of the bowels The presence of such casts of dried mucus and cellular debris stained with fecal content does not basically differentiate this condition from the other types however because the secretion of mucus is a normal response of the bowel to irritation Less definite terms frequently used such as dyspepsia nervous indigestion gastric neurosis intestinal neurosis and so on do not all have identical connotations but fundamentally and practically the problems presented are the same and hence they may all be grouped together The condition is characterized by an abnormal irritability of the bowel with resultant abdominal distress and alteration in function The altered function consists of increased tone and motility with irregular and intermittent spasm

Etiology —In the absence of disease abnormal irritability may be related either to an excessive irritant such as laxative foods cathartics and enemas or to emotional disturbances or to a combination of the two The ability of castor oil and of fear to produce diarrhea are well established facts The chronic effects of laxative foods and of the emotional reactions to the difficulties of life are in certain individuals equally definite Symptomatically one sees all gradations from the chronic distress and diarrhea induced by the continued use of cathartics to the chronic complaints of the hypochondriac Usually it is difficult to differentiate sharply the physiologic and the psychologic or emotional factors and indeed as a rule it is unneces ary to do so Most important and never to be forgotten is the fact that distress of bowel origin and therefore technically bowel distress may accompany a variety of organic diseases Thus the cramps of bacillary dysentery or of intestinal obstruction are 'bowel but obviously not functional Physiologic toxic or reflex disturbances of the colon are seen in such diseases as pernicious anemia thyrotoxicosis pulmonary tuberculosis and pellagra These conditions are not included in the subject under discussion but the digestive symptoms may be confused

Symptoms —The symptoms of functional bowel distress vary in severity from fulness and discomfort induced by the ingestion of food or drink to severe cramplike abdominal pain This tends to be generalized over the abdomen may shift from point to point and usually is more noticeable in the lower than in the upper abdomen As a rule defecation or the expulsion of flatus affords temporary relief occasionally however the passage of a bowel movement inaugurates more vigorous cramps and tenesmus Nausea is a frequent symptom Many patients complain that they are unable to eat a full meal without experiencing an unpleasant sen a tion of fulness and distention perhaps sufficient to force them to discontinue the meal Belching rumbling and gurgling in the abdomen and excessive flatus are frequently noted Constipation is usually said to be present the patient meaning that it is neces ary to take laxatives or enemas in order to obtain a bowel movement When one inquires as to how long the patient goes without a defecation the typical response is 'I never let my bowels go more than a day without moving Thus patients say they are constipated whereas in fact they maintain a state of chronic diarrhea Many patients are obsessed with notions concerning the desirable frequency of defecation such as one after each meal or with ideas as to the optimal quantity assuring the physician dolefully that their bowels do not move enough Such patients are satisfied as a rule only by copious watery evacuations Inquiry into the type of stool passed usually discloses the fact that some abnormality is present such as loose watery stools unformed stools narrow ribbon like or lead pencil sized stools or hard dry balls The classic stools of lead colic are seen nowadays not in lead colic as a rule but in these functional disturbances The hard dry constipated stools when accompanied by abdominal distress are usually due to spasm—hypertonicity rather than atonicity Headaches fatigue and countless other nervous manifestations frequently present in such cases are not to be interpreted as due to alleged constipation or intestinal toxemia These symptoms as well as the bowel distress are usually on a functional" nervous or emotional basis It is surprising to note how frequently the therapeutic program outlined benefits them as well as the function of the digestive tract

Physical examination usually reveals a well nourished individual but occasionally

extreme grades of chronic malnutrition are noted The colon is often palpable and tender particularly the sigmoid portion Proctoscopy discloses a normal rectum and sigmoid The laboratory and roentgenologic findings are entirely normal Frequently the colon when examined with the barium enema exhibits evidence of hyperirritability, waves of mass peristalsis may be noted and the patient may complain of severe pain However, these changes are not sufficiently constant definite or regular in their appearance to justify reliance upon the roentgenologic diagnosis of an irritable colon

Diagnosis.—The diagnosis is based upon a history of catharsis or enema habit dietary indiscretion or emotional strain generalized or lower abdominal distress of the type described abnormality of the bowel movement and tenderness along the course of the colon

Differential diagnosis involves first the search for organic disease of the digestive tract *Carcinoma of the colon* particularly of the rectosigmoid should be excluded by examination of the stool for occult blood by x ray and by proctoscopy *Diverticulitis* may be detected by x ray although the mere demonstration of diverticulosis is not particularly significant *Ulcerative colitis* may be detected proctoscopically *Regional enteritis* may be suspected if the distress tends to be periumbilical or if there is roentgenologic evidence of a lesion of the small bowel *Carcinoma of the stomach* occasionally produces diarrhea and lower abdominal distress as does *carcinoma of the pancreas* The pain of *peptic ulcer* may be masked by bowel distress which may persist after the ulcer heals Cirrhosis of the *liver* passive congestion of the liver tuberculosis and carcinomatous *peritonitis* and other nondigestive diseases may be accompanied by these rather vague abdominal symptoms *Gallbladder disease* presents one of the most interesting diagnostic problems Acute bowel distress may simulate biliary colic On the other hand patients with cholelithiasis not infrequently have two types of distress (1) biliary colic and (2) so called biliary dyspepsia consisting of belching upper abdominal fulness and distention and aversion for fried or fatty foods The biliary colic is cured by cholecystectomy the dyspepsia frequently is not and may be relieved even without cholecystectomy by the program used in the management of bowel distress. The latter statement applies also to the alleged dyspepsia of so called noncalculous cholecystitis In fact it is doubtful whether gallbladder disease really produces dyspepsia at all The problem is similar to that which arises in connection with the appendix Acute and subacute and so called interval appendicitis produce the classic symptomatology of acute appendicitis Chronic appendicitis on the other hand may be found pathologically in a very high percentage of individuals with bowel distress just as it may be found in a high percentage of normal individuals Removal of the appendix or of a normal gallbladder or a diseased gallbladder is followed by good results in some cases and by bad results in others irrespective of the condition of the organ removed The major psychotherapeutic effect of an operation must always be borne in mind and care exercised in the drawing of *post hoc ergo propter hoc* conclusions The distress of these allegedly specific dyspepsias can usually be relieved by nonspecific measures A similar problem is presented by the gastritides found by the gastroscopists in approximately 40 per cent of all patients gastroscoped because of abdominal distress Except for certain erosive forms the relationship between the disease and the distress seems highly questionable Many of these patients present other manifestations of the irritable colon syndrome and respond very well to management Some physicians regard all patients included in the bowel distress group as psychoneurotics The great majority of them however pass for normal even as you and I some are frank psychoneurotics, others are hysterical a few are hopeless hypochondriacs some are more or less profoundly depressed some are psychotic

Treatment—Actually the first step in treatment is the relief of the patient s anxiety concerning organic disease Definite reassurance that there is no cancer or ulcer or some other serious condition cannot be given convincingly unless the examination has been detailed and careful Some patients however react with disappointment their thought being that they are ill that they

have pain and yet nothing has been found to be wrong It is then necessary to explain in detail the nature of the disorder, the cause of the pain and to outline the procedures for obtaining relief Superficial psychotherapy such as this is usually sufficient but frequently a deeper analysis of the patient and his problems is required In almost all cases in which the therapeutic program to be outlined is found ineffective the cause will be discovered to be either an unrecognized organic disease or a difficult often impossible psychiatric status

Laxatives and Enemas—The patient should be educated to obtain satisfactory bowel movements without the use of laxatives Hence cathartics of all kinds including mineral oil should be discontinued Diarrhea may ensue and may be controlled by regulation of the diet and by the drugs mentioned More frequently the patient will be surprised by the development of a normal bowel function Several days may elapse without defecation this is not alarming provided the rectum remains empty The only difficulty to be avoided is the development of a fecal impaction in the rectum Patients usually recognize the presence of such rectal masses but they may fail to do so Indeed not infrequently cramps and diarrhea result from the presence of a rectal impaction Consequently in the interval while waiting for the bowels to move digital rectal examinations should be made once or twice daily Ordinarily there is no danger in waiting several days even a week or two for feces to come down into the rectum but if a rectal impaction develops it should either be removed or broken up digitally following which a large tap water or soapsuds enema should be given repeatedly if necessary until the rectum is empty Oil retention enemas are of little if any value for this purpose but may be given prophylactically Three ounces of olive or mineral oil may be injected into the rectum at bedtime and retained over night if there has been no stool at all during the day or if the stool has been very hard and dry If no stool is passed by the following forenoon a small water enema (1 pint) may be given

Some individuals lose the normal defecatory reflex and are regularly unable to evacuate the stool—a so called *rectal dyschezia* Glycerin suppositories used at a regular hour are often helpful in re establishing the reflex Occasional patients solve this problem best by the daily use of a small enema half a pint or a pint of tap water Finally it should be pointed out that certain elderly people without abdominal distress should be permitted to continue their cathartic habit If they have no pain and have adopted a regime satisfactory to them there is no need to meddle with it

Rest and Exercise—In patients with a very irritable colon rest is of great value and conversely in patients with atonic constipation exercise is helpful The amount of rest indicated depends upon the severity of the disturbance When the pain is severe complete bed rest is in order In the average case long hours of sleep at night and perhaps a nap or rest period in the afternoon are adequate The application of heat to the abdomen in the form of hot stupes or more simply and conveniently an electric pad or a hot water bottle is advisable

Diet—The dietary management of bowel disturbance is based upon the varying laxative effects of different foods Anything which stimulates peristalsis may produce spasm and disordered function in a sensitive intestine Hence the diet must be adjusted to the sensitivity or irritability of the bowel All foods stimulate intestinal activity and thus are laxative There are no really constipating foods but there are marked quantitative differences in the effects of different ones There are also qualitative differences in their action just as there is a difference in the effect of magnesium sulfate and castor oil The irritative action of foods may be of a mechanical or chemical nature The classification on pages 716 and 717 is derived from tradition and experience

The average patient may be best handled by prescribing a diet estimated to produce the laxative effect required Thus temporarily he may be advised to select his diet from the first four sections only and be instructed specifically to eat a stipulated amount of cooked vegetable and cooked fruit perhaps two dishes of each daily a dish containing a liberal serving of approximately 100 Gm (3⅓ ounces) If diarrhea and abdominal distress continue on this

I *Foods with Little Irritant and Hence Best Tolerated in Acute Disturbances*

Water weak tea rice or barley gruel meat broth cream of wheat oven toasted toast, zwieback or toasted soda crackers with butter soft cooked eggs boiled milk custard plain jello

II *More Substantial but Relatively Bland and Easily Digestible Foods*

Cereals with milk or cream
- Refined rice
- Rice Krispies
- Rice Flakes
- Puffed Rice
- Cornflakes

- Cottage pudding
- Peter Pan cookies
- Hydrox cookies
- Arrowroot cookies
- Custard
- Chocolate

III *Cooked Vegetables—More Laxative Chiefly Because of Greater Residue*

A Moderately irritating
- Asparagus
- String beans
- Carrots
- Spinach
- Sweet potato
- Peas
- Tomatoes
- Beets

B More irritating
- Artichokes
- Parsnips
- Onions
- Cabbage
- Cauliflower
- Rutabaga
- Eggplant
- Green peppers
- Turnips
- Kohlrabi
- Broccoli
- Navy beans
- Lima beans
- Squash
- Corn

IV *Cooked Fruit More Laxative Because of Chemical Irritants*
- Prunes
- Peaches
- Applesauce
- Figs
- Apricots
- Pears
- Baked apple
- Plums
- Cherries
- Berries of all kinds
- Grapes
- Pineapple
- Rhubarb
- Fruit pies

V *Raw Vegetables More Laxative*
- Lettuce
- Celery
- Watercress
- Endive
- Tomatoes
- Radishes
- Onions
- Cabbage
- Cucumbers

VI *Raw Fruits More Laxative*

Banana (least laxative)	Pears
Oranges (juice sections whole)	Peaches
Grapefruit (juice sections whole)	Cherries
Apples	Grapes
Melon	Plums
Pineapple	Apricots
Berries of all kinds	Avocado pear

VII *Miscellaneous Foods Some Very Laxative Such as Honey and Beer*

Ice cream with fruit	Pickles olives relishes
Ice cream with nuts	Catsup
Jam, jelly marmalade honey	Soft drinks Coca Cola gingerale, sodas
Syrup	Alcoholic beverages beer wine, whiskey etc
Nuts	
Pop corn	
Candy	

schedule the fruit and vegetable content may be eliminated completely On the other hand it may be necessary to increase the intake of vegetable and fruit to three dishes daily specifically including liberal servings of spinach and prunes head lettuce and celery at least once per twenty four hours Usually it is not difficult to restore normal bowel function within a few days and to relieve the distress The diet should be continued for a few days or weeks before the patient gradually returns to a full menu Many individuals find it necessary to maintain some dietary restrictions permanently if they are to live comfortably Persistent pain and discomfort in the presence of normal bowel function is rarely of bowel origin There is no difficulty as a rule in selecting a diet adequate in caloric and vitamin requirements except in individuals with acute disturbances who are able to tolerate only a few of the foods outlined in section I Caloric deficiencies may usually be tolerated safely for the number of days required for the irritability to subside Vitamins may be administered hypodermically as desired although in the average case they are needed for a short time only

Drugs—The drugs of greatest value are the antispasmodics Tincture of belladonna is the standby given in doses of ten to fifteen drops three or four times daily Atropine is equally satisfactory 1/100 or 1/150 grain (0 0005–0 0004 Gm) three or four times daily In acute conditions 1/60 grain (0 001 Gm) may be given hypodermically Numerous atropine like preparations alleged to give superior effects on the bowel with fewer unpleasant side reactions such as dryness of the mouth and blurring of vision are of questionable superiority The barbiturates are very valuable and may be used in conjunction with belladonna 1/4 to 1/2 grain (0 015–0 03 Gm) of phenobarbital being given three or four times daily If insomnia is present the phenobarbital may be given to advantage at bedtime rather than throughout the day The drug exerts a desirable sedative effect not only on the general nervous system but also upon the bowel itself Bromides are equally satisfactory except for the hazard of bromoderma Opiates are as a rule to be avoided for they increase the tonicity of the gut Acute diarrheas are sometimes checked by opium or by morphine but the effect is accomplished by increasing the tone throughout the bowel and decreasing the peristaltic activity In chronic cases this effect in addition to the habit forming aspect is undesirable Codeine in doses of 1/2 to 1 grain (0 03–0 06 Gm) is much less objectionable and indeed at times is very helpful Paregoric although commonly used is not recommended for its active constituent is opium and few who use it know just how much opium it contains

DILATATION OF THE COLON

It is sometimes hard to decide whether a colon is normal or dilated This difficulty arises from the fact that in normal individuals it varies enormously in size and hence differences of opinion naturally arise as to whether a given colon is dilated or merely normally large and tortuous The important consideration however, is not the size but rather the function of the colon Pathologic dilatations may be divided into (1) gaseous, (2) obstructive, and (3) megacolon or Hirschsprung's disease

Gaseous Distention —This is at times one manifestation of the functional bowel distress syndrome The more severe types occur as paralytic ileus following abdominal operations, as a complication of peritonitis, or of any febrile illness such as lobar pneumonia The distention of the abdomen pushes up the diaphragm, interferes with respiration and hence may present a serious complication

Treatment in the milder cases consists of the application of heat to the abdomen in the form of hot stupes or an electric pad and the limitation of oral intake to small amounts of warm nonirritating food such as barley gruel tea cream of wheat toast soft cooked egg Belladonna and phenobarbital are helpful because there is usually localized spasm as well as dilatation In the more severe grades nothing should be given by mouth A rectal tube may facilitate the escape of gas Enemas are frequently given usually of soapsuds or so called 1 2 3 enemas These frequently help the patient to expel considerable amounts of gas but at times they increase the pain and discomfort Morphine sulfate $\frac{1}{6}$ to $\frac{1}{4}$ grain (0 010 to 0 015 Gm) usually gives great relief and by increasing the tonicity of the gut helps the patient to expel gas Physostigmine in doses of $\frac{1}{30}$ grain (2 mg) subcutaneously and prostigmine 1 cc of a 1–2000 solution may be tried but are *not always effective* The inhalation of oxygen is often followed by dramatic improvement

The dilatation secondary to obstruction identified by locating the obstruction usually in the sigmoid or rectum ordinarily requires *surgical relief* although decompression of the *distended* loops of small intestine and colon by means of the Miller Abbott tube may be a life saving measure This procedure must be carried out however *with patience* and perseverance by someone who knows and understands the technique

Megacolon or Hirschsprung's Disease — *This is a congenital idiopathic* dilatation of extreme grade usually found in children In some cases the dilatation and hypertrophy *terminate at the rectosigmoid* in others they extend to the internal sphincter of the anus The child is usually stunted the abdomen is *relatively enormous, weeks or months* may elapse without a bowel movement As a rule the colon may be emptied by means of numerous *enemas and laxatives Some* patients continue to empty the bowel in this way taking a daily dose of senna by mouth and *supplementing its effect with two or* three enemas Various surgical procedures have been devised, the most radical being extirpa*tion of the colon and the most* satisfactory being section of the lumbar sympathetic nerves Spinal anesthesia alone temporarily *increases the activity of the colon* in such patients Neurectomy seems to be much more satisfactory in children than in adults

DIVERTICULA OF THE INTESTINES

Meckel's diverticulum is the only significant diverticulum occurring in the jejunum or ileum It is a remnant of the omphalomesenteric duct which normally disappears within a few weeks after birth Not infrequently however it persists *more or* less completely as a fibrous tube *or cord*

arising usually from the ileum two or three feet from the ileocecal valve with or without a distal attachment to the umbilicus It may cause volvulus strangulation or intussusception

Acute inflammation of Meckel s diverticulum differs from acute appendicitis only in a more central periumbilical location of the pain—a differential point not too reliable Operation is indicated

Meckel s diverticula may contain islands of aberrant gastric mucosa secreting acid gastric juice Peptic ulcers developing in the mucosa of the ileum adjacent to the stoma of such diverticula are a common source of melena in infants and children and may occur in adults

Diverticulosis is a term used to denote the existence of diverticula The etiology is not known The incidence of diverticulosis in adults is approximately 5 per cent (Mayo Clinic) It is rare in children uncommon in young adults and occurs in increasing frequency with each advancing decade of life The descending colon and the sigmoid are involved most frequently and most extensively Diverticulosis is a silent benign condition frequently found in patients with bowel distress and apparently playing no role in the distress In *treatment* the diverticula may be disregarded

Diverticulitis occurs in only a small fraction of patients with diverticulosis It may be acute or chronic mild or severe Simple inflammation is likely to be associated with spasticity of the colon and hence simulates a spastic sigmoid When the inflammation is more acute signs of peritoneal irritation develop such as localized tenderness and muscle spasm Perforation may occur with localized peritonitis and abscess formation or generalized peritonitis Fistulae occasionally develop between the sigmoid and the urinary bladder as is indicated by the passage of urine containing gas or fecal material Obstruction may result from the intramural inflammation Ulceration of the mucosa is rare and hence rectal bleeding is usually due to hemorrhoids fissure of the anus or carcinoma The diagnosis is usually made by the history of recurring cramplike lower abdominal pains with tenderness and perhaps rigidity in the left lower quadrant and by the roentgenologic demonstration of diverticula with distortion of the pattern of the mucosal folds and an extensive ragged deformity of the contours of the bowel A mass in the sigmoid may be detected by abdominal palpation or by rectal examination Fever and leukocytosis may be present Neoplasm usually listed as a sequel of diverticulitis is probably merely a coincidence

The *treatment* of diverticulitis is rest in bed with heat (hot stupes electric pad or hot water bottle) applied to the abdomen The same dietary and medicinal principles may be applied as outlined in the section on functional disturbances of the colon Mineral oil may be given in doses of 1 or 2 ounces (30 to 60 cc) daily In rather rare cases the obstruction is sufficient to require either a permanent colostomy or resection of the most stenotic portion of the bowel

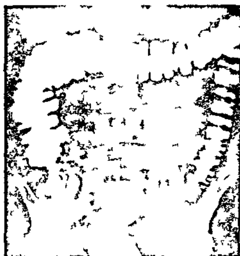

Fig 71—Chronic diverticulitis of the sigmoid. Patient J O (Unit No 237° 0) Male forty six years of age entered the hospital because of cramping lower abdominal pain of one week s duration The pain was sharp intermittent, relieved by the passage of flatus or feces A similar attack with leukocytosis seven years earlier had been treated by appendectomy but the *pain did not disappear until three weeks after the* operation A second attack four years later subsided spontaneously The stools in the present attack were described as watery Marked tenderness and moderate rigidity were present in the lower abdomen particularly on the left The temperature was normal and remained so the leukocyte count was 20 300 dropping to 11 000 on the third day The pain and tenderness subsided rapidly Note the coarse sawtooth appearance of the sigmoid

NONSPECIFIC ULCERATIVE COLITIS

Nonspecific ulcerative colitis is an inflammatory disease of unknown etiology It may be limited to the rectum or involve the entire colon and even the terminal ileum The process is characterized initially by a friability of the mucosa with hyperemia and minute superficial bleeding ulcerations In fatal cases the entire colon is almost invariably involved and frequently there are one or more areas of disease in the small bowel The colon may be almost denuded of mucosa only occasional islands being left The areas of perforation found at autopsy may be so extensive as to suggest an autolytic process In less dramatic cases the longitudinal character of the ulcers suggests that pressure necrosis resulting from continued spasm may be a factor The degree of cellular reaction evident histologically in the wall of the bowel is quite variable often being surprisingly little and consisting chiefly of round and plasma cells with moderate numbers of leukocytes The disease seems to be increasing in frequency although as in so many conditions it is difficult to determine whether it is actually more prevalent or is merely recognized more frequently It occurs in both sexes and at all ages but particularly in the second third and fourth decades

Symptoms —The most benign type of the disease is that in which the inflammatory process is mild in severity and limited to the rectum or rectosigmoid In such cases the only symptom is the passage of red blood with each bowel movement The stools are usually well formed or even hard and dry Bloody mucus may be expelled without stool The presence of diarrhea usually indicates a more extensive involvement of the colon The number of stools may reach 15 to 20 per day or more with rectal incontinence There may be no pain at all and no abdominal tenderness in marked contrast to the spastic bowel In other cases cramps or tenesmus or both may be present and may be intense Fever occurs in the more severe cases leukocytosis is uncommon Loss of appetite is frequent, nausea and vomiting occur occasionally In the severe fulminating cases the onset is usually acute and the course rapid and severe with continued diarrhea inability to eat fever weakness anemia and profound debility Death may result from exhaustion or from perforation of the colon and generalized peritonitis The less severe cases may recover completely, more frequently they recover and then relapse occasionally they reach a stage of chronic invalidism with two or three somewhat bloody stools daily, roentgenologic and proctoscopic evidence of continued disease but without complete disability The more frequent complications are severe anemia perianal abscess perforation of the colon with local abscess formation or generalized peritonitis stricture formation polyposis of the bowel and rarely carcinomatous degeneration of the polyps

Theories of Causation —In general the theories concerning etiology may be divided into those relating to (1) infection and (2) emotion Pathologically and clinically the disease is indistinguishable from chronic bacillary dysentery except by positive bacteriologic evidence The well recognized difficulty encountered at times in isolating organisms of the dysentery group from cases of bacillary dysentery led early workers to look upon ulcerative colitis as chronic bacillary dysentery Apparently in the tropics there are numerous cases of chronic dysentery in which no pathogenic organisms are demonstrable A very attractive hypothesis suggests that the disease process is initiated by a specific dysentery and then maintained by ordinarily nonpathogenic organisms Felsen presented evidence that ulcerative colitis developed in a small percentage of people

afflicted with bacillary dysentery Occasional cases of amebic colitis are seen in which the colitis persists after the eradication of the amebae Numerous workers have found (a) that pathogenic organisms and parasites are present in only a small percentage of the cases of presumed nonspecific ulcerative colitis and (b) the serum of such patients does not contain in significant titer the antibodies of the known pathogens Endless search has been made for other possible etiologic organisms Hemolytic and nonhemolytic streptococci and staphylococci are frequently found diplococci and *B coli* are invariably present *Bacterium necrophorum* can usually be cultured if one uses the proper technic but none of those organisms has as yet been accepted as the causative agent or proved capable of producing the disease with any regularity in the experimental animal

The concept of a *psychogenic cause* is based on certain clinical and experimental evidence There is the well recognized capacity of fear to produce diarrhea Many patients afflicted with ulcerative colitis have very definite personality disorders Occasionally the relation between an emotional disturbance and an exacerbation of the disease seems too direct to be merely coincidence On the other hand the so called functional disorders of the colon almost never develop into ulcerative colitis and conversely the latter usually develops in individuals without previous digestive symptoms Experimentally Lium has produced ulceration of the intestinal mucosa as a result of spasm but the significance of this observation remains to be determined

Diagnosis—The diagnosis is established by a history of the symptoms described by the demonstration proctoscopically of a diffusely granular friable superficially ulcerated and bleeding mucosa and by the failure to find a specific cause for the inflammation The stool and also rectal swabs should be cultured for pathogenic organisms and a careful search made for *E histolytica* Usually if amebic colitis involves the rectum the ulcers are easily identified by their sharply punched out appearance the peripheral red halo and the areas of perfectly normal mucosa intervening between the ulcers but occasionally the picture is confusing The roentgenologic appearance is not pathognomonic Classically the colon loses its haustral markings decreases in caliber and in length and becomes somewhat fuzzy in outline

If the cecum and ascending colon are the portions of the bowel most extensively involved the possibility of tuberculous enteritis or amebiasis should be seriously entertained If the disease is limited to the rectum sigmoid and lower descending colon the roentgenologic appearance may be normal Conversely erroneous positive diagnoses may be made because the normal descending colon and sigmoid devoid of haustrations frequently present the straight tube like appearance considered typical of ulcerative colitis Lymphopathia venereum may produce a proctitis and sigmoiditis proctoscopically identical with the nonspecific form but usually stricture formation is present A history of buboes suggests and a strongly positive Frei test almost proves the diagnosis of lymphopathia venereum

Treatment—There is no specific therapy In the acute and subacute phases rest in bed is very important The application of heat to the abdomen in the form of an electric pad or a hot water bottle is helpful The diet should be as nonirritating yet as nutritious as possible (See Functional Bowel Disturbances) Meat is well tolerated The patient s weight and caloric intake should be watched constantly Accessory food factors should be given as indicated to compensate for the low intake and the possibility of poor absorption When bleeding is present a low prothrombin time is occasionally found indicating a need for vitamin K Belladonna may be used in large doses (40 to 120 drops per day) as tolerated Phenobarbital ½ grain (0 03 Gm) four times daily is valuable for its general sedative effect and for its effect upon the bowel Bismuth and chalk powders (bismuth subcarbonate calcium carbonate and calcium phosphate each 1.5 Gm) are usually not of much value but may be tried Opium may temporarily diminish the diarrhea but it is not recommended because it increases the tonicity of the bowel Occasionally however codeine in doses of ½ grain (0 03 Gm) when given with atropine or belladonna may be helpful Transfusions of whole blood or of plasma are of very great value Anemia is likely to appear early

and to become quite profound partially due to the inanition but more particularly to the continued loss of blood Consequently transfusions of whole blood are preferable they should be given in large amounts 500 cc to 600 cc at a time and as frequently as necessary to maintain a normal blood picture Various sulfonamides (neoprontosil sulfanilamide sulfadiazine sulfathiazole

fect the course of the disease Ileostomy m be indicated in the chronic cases not in fulminating ones for in these the patien chance of recovery is as great if not grea without surgical interference If after ile tomy active severe disease persists as e denced by recurring attacks of chills a fever or arthritis and bloody rectal d charge colectomy may be indicated Rare

Fig 72—Chronic ulcerative colitis Patient L G (Unit No 110985) a female twenty-one years of age entered the hospital in August because of bloody diarrhea and a 32 pound loss of weight The first symptom in January consisted of the passage of red blood in every stool In March appendectomy was performed for acute appendicitis Diarrhea appeared the day after the operation and persisted until admission averaging about ten watery bloody stools per day Lower abdominal cramps accompanied the diarrhea Twelve injections of emetin hydrochloride were given in June although *E histolytica* were not found Emaciation was evident, the abdomen was rather scaphoid and tender pitting edema was noted in both feet Red blood corpuscles, 2 9 million hemoglobin 52 per cent white blood corpuscles 14 100 Repeated stool examinations were negative for parasites and pathogenic bacteria but disclosed gross pus and blood During the first week of hospitalization the temperature ranged to 102 F then subsided During the subsequent eight months of hospitalization there were occasional febrile periods lasting one or two weeks the diarrhea gradually subsided the appetite and intake of food increased as did the weight The patient remained in bed at home for most of the time through the ensuing year the stools continuing to be well formed and without blood In the subsequent six years there have been occasional brief recurrences of blood in the stool with or without diarrhea Proctoscopic examination at such times has disclosed a granular friable mucosa with multiple small bleeding points at other times the mucosa of the rectum has appeared normal or slightly scarred The patient is working and seems in excellent health The roentgenogram on the left shows the shortened colon devoid of haustrations with an abnormal mucosal pattern throughout the transverse portion the picture on the right taken six and a half years later discloses a longer colon of normal caliber with a return of haustra in the transverse section

sulfaguanidine sulfasuccinyl and others have been tried extensively As is usually the case in any chronic relapsing disease 'good results have been reported It is clear however that few if any miracles have been wrought although some patients do seem to have been benefited The bacterial flora of the feces is altered markedly the normal coliform organisms being replaced by cocci and the total bacterial count greatly reduced These changes do not seem to af

is it feasible to restore the normal continuity of the bowel

Finally it should be emphasized that in few diseases is there required more patience and perseverance The treatment as in pulmonary tuberculosis must be continued for months and years most carefully and yet most tactfully In few conditions is there more need for the art of medicine

REGIONAL ILEITIS

Definition —Regional ileitis is a nonspecific inflammation of the distal loops of the small intestine involving mainly the terminal segment and characterized by the formation of an ulcerating proliferating and cicatrizing granulomatous mass in this area Fistulous tracts from the ileum to the abdominal wall and from ileum to other adjoining hollow viscera commonly characterize the disease

Clinically the disease presents the picture of a low grade chronic infection of slowly progressive nature and ends by causing intestinal obstruction or lacking that by eventual inanition and exhaustion

Etiology —The disease is one of youth although its range throughout life is extensive The youngest case reported was eight years the oldest seventy one years of age The vast majority of cases fall into the decade between twenty and thirty years of life the average of a large series being twenty seven and one half years Ileitis is restricted to no geographic locality nor to any race or nationality It is now recognized through worldwide publications and case reports that the disease is probably universal in its distribution

No known single bacterial agent or virus can be held etiologically responsible for ileitis The disease is definitely not tuberculous since inoculations of laboratory animals with intestinal material repeatedly fail to demonstrate tuberculosis There may possibly be an association of ileitis with the dysentery bacillus some of the cases show fair serum agglutinations (1 80–1 160) and an occasional *Shigella dysenteriae* has been recovered from the stool The claim has also been made that ileitis like colitis has followed epidemics of intestinal dysentery Proof to date is lacking However multiple cases of ileitis in the same family have occurred five times in the last few years (brothers sister and brother two sisters and a niece etc) so that the suspicion of a common infectious agent seems justifiable

Morbid Anatomy —The granulomatous inflammation begins most often flush with the ileocecal valve and extends for 6 8 10 or 12 inches in an oral direction as a continuous cobblestone like ulceration accompanied by a dense thickening and infiltration of the submucosa muscularis and serosa Thence upward the areas of involvement may be interrupted to form skip areas separated by variable distances of apparently normal mucosa (12 18 or even 30 inches of uninvolved intestinal surface) Enlarged succulent mesenteric lymph nodes accompany the areas of intestinal involvement

The disease is not limited to the terminal ileum occasionally one sees the whole ileum or the ileum and the lower jejunum or the upper ileum and the whole jejunum involved a most unusual form is an involvement of a localized few inches isolated in some upper segment of ileum or jejunum the terminal ileum remaining free of disease

The cecum and the colon are rarely implicated only exceptionally does the process pass the ileocecal barrier to involve the cecum and ascending colon These are known as cases of combined ileitis and colitis or often as colo-ileitis

The slow perforation from a porous ul

cerated ileum may result in one of the most characteristic features of the disease namely, fistula formation These fistulas begin in the diseased ileum at the mesenteric attachment, they may end on the abdominal wall, particularly in the scar of a previous laparotomy or in any internal hollow viscus such as another intestinal loop a segment of colon or sigmoid the urinary bladder ureter, vagina or uterus

Quite commonly and very early in the course of the disease these fistulous tracts may appear as perirectal, rectal or rectovaginal fistulas preceding or accompanying the onset of active clinical manifestations of the disease

Symptoms —The commonest form of ileitis is the low grade chronic granulomatous type But acute ileitis does occur and is characterized by the sudden onset of severe cramps localized in the right lower quadrant, with fever ranging up to 102° to 103° F leukocytosis and mild usually unnoticed diarrhea The abdominal muscular rigidity tenderness and rebound tenderness simulate acute appendicitis and as such the case is usually operated upon as one of acute abdomen At the laparotomy the appendix is found to be normal the ileum beefy red and injected The mass is usually with good judgment returned to the celiac cavity resection is inadvisable and dangerous Such cases frequently subside and probably return to a normal status or they may progress to the more familiar and chronic form of ileitis

Chronic regional ileitis is characterized by a prolonged history covering several months or years of diarrhea abdominal pain loss of weight anemia fistula formation and eventually symptoms of intestinal obstruction The diarrhea consists of three to five or more mushy or semisolid stools containing mucus pus and occasionally gross blood The movements are accompanied by generalized abdominal cramps usually more marked in the lower quadrants Vomiting is unusual On abdominal examination a mass may frequently be felt in the right lower quadrant often in the region of the appendix or cecum but sometimes in the midline above the bladder or even in the sigmoid area The mass may be the size of a lemon or more often of a small orange tender and fixed Occasionally one may feel the gurgle of the passage of gas and fluid through the contracted intestinal lumen of the area under palpation

Approximately 10 per cent of cases of ileitis go on to eventual partial intestinal obstruction of a subacute severity Such obstruction is the end result of many years of ulceration and cicatrization and represents the attempt at healing and scar formation with encroachment upon the lumen of the intestine Obstruction is occasionally an initial symptom particularly in those cases in which the onset is acute and febrile In these instances the pathologic changes in the small intestine are usually extensive reach high up into the upper ileum and are based upon a diffuse inflammatory granulomatous change in the intestinal wall with considerable edema

The general condition of the patient suffers considerably but slowly as the disease progresses from year to year The loss of weight may be severe in older persons simulating carcinomatous cachexia anemia is moderate mild leukocytosis the rule particularly during the acute recurrences Minimal or occult blood in the stool is usual but gross hemorrhage from the bowel most exceptional

The course of chronic ileitis is a slowly progressive one spontaneous resolution rarely ensues Slow perforation in the right lower quadrant of the abdomen with localized peritonitis may occasionally end fatally More usually external fistulas or perirectal abscesses and fistulous tracts imperil nutrition and cause inanition and anemia

Diagnosis —The presence of an ileitis is based upon the finding of

1 A tender fixed mass in the lower abdomen

2 The presence of external fistulous tracts or perirectal abscesses or fistulas

3 Diarrhea milder than in colitis often intermittent

4 A low grade irregular fever

5 A negative sigmoidoscopy which should exclude the more common forms of ulcerative colitis

The clinical symptoms and the physical examination in a young person should suggest strongly the diagnosis which however should be confirmed by a thorough radio-

graphic study For this purpose a barium enema or preferably a barium meal should be instituted The barium enema should be continued until ileocecal regurgitation reveals the terminal ileum The barium meal should be followed hourly for three four five six, or seven hours until the terminal ileum is filled and visualized and photographed

In ileitis the terminal ileum presents the string sign of a distorted narrowed irregular lumen with the loss of mucosal pattern usually a six to nine hour delay in the distal ileum is observable Not every x ray is however confirmatory of the diagnosis at times the clinical impression is so positive that even in the absence of radiographic confirmation laparotomy is advisable

Ileitis is to be differentiated from sprue from primary ileocecal tuberculosis (an extremely rare disease) from diffuse Hodgkin s disease and disseminated lymphosarcomatosis of the small bowel Carcinoma of the ileum or jejunum is also much less common than ileitis and is difficult to differentiate In comparison with any of these diseases ileitis occurs with much greater frequency particularly in younger persons Its course is prolonged and indolent extending over years and rarely so severe or rapidly down hill as sarcoma Hodgkin s disease or carcinoma

Prognosis—The prognosis in ileitis is good as to life particularly in those patients in whom the process is limited to the terminal ileum and in which resections or short circuiting operations can successfully be performed In the complicated cases with fistulae to the external abdominal wall or to the internal viscera the prognosis while still good is altered by the complexity of the pathologic process The cases of diffuse ileo jejunitis offer in spite of extensive involvement a fairly good prognosis Diffusion of the process with its broad skip areas lessens the intensity of the disease at any one point The outlook under conservative medical care is comparatively good both as to life and as to healing of the inflammatory process

Treatment—No satisfactory medical treatment exists Supportive or expectant treatment in the form of a nonroughage diet vitamin replacement transfusions and sunshine help build up the general condition but the eventual therapy should be surgical

Chemotherapy—The use of some of the more recent sulfa drugs has been attempted in ileitis In general the results have been discouraging However in the cases of diffuse ileo jejunitis where surgery is obviously out of the question succinyl sulfathiazole (sulfasuxidine) is well worth a trial In several cases its use has led to apparent clinical betterment

Surgery—First choice is radical resection of the diseased terminal ileum cecum and ascending colon and the formation of an ileo transverse colostomy This is feasible and with comparatively low risk (approximately 10 per cent fatality) in most cases where the process is still a limited one and where too many fistulous tracts too extensive an intestinal involvement or a localized peritonitis has not yet occurred The resection must include all higher skip areas in the bowel lest recurrences appear at a later date

In cases where fistulous processes and infiltrating suppurative foci have occurred in the lower right pelvis primary resection is dangerous A short circuiting operation in such instances should generally be followed by a resection of the original process It is likely that the mesenteric lymph nodes represent the foci of residual infection and as in carcinoma these nodes serve as the point of origin of subsequent recurrences in the areas proximal to the surgical anastomoses For this reason wherever possible a primary resection with removal of all large succulent lymph nodes offers the very best chance for permanent cure

Where resection seems impossible or too dangerous an ileocolostomy with transection of the ileum is the second best choice The ileum must be cut across above the uppermost area of involvement so as to isolate and shut off the diseased area The ileocolostomy may be performed in the ascending or transverse colon or in the sigmoid

These short circuiting or palliative operations have a slightly lower mortality rate but are successful only in about 50 per cent of the cases When the symptoms continue in spite of such a conservative procedure a secondary resection of ileum and ascending colon is mandatory

Recurrences after resection are unfor

tunately too frequent (almost 15 per cent) and can be avoided only by making the original procedure so radical as to surely include in the excision all diseased areas

APPENDICITIS

Definition —Appendicitis the most common major surgical disease is an inflammatory lesion of the vermiform appendix It may occur as an acute attack acute appendicitis which progresses to perforation or subsides spontaneously as mild recurrent attacks recurring appendicitis or if adhesions or obliteration follow infection a so called chronic appendicitis

History.—Laurence Heister[1] in 1711 found an abscess of the appendix at autopsy which he described in his Chirurgische Warnehmungen From the time that Mestivier[2] in 1759 demonstrated at autopsy an appendiceal abscess originating from a pin in the appendix the abscess having been surgically drained 141 cases of disease of this viscus were recorded in the literature before the paper of Reginald Fitz[3] in 1886 Fitz defined appendicitis and analyzed 257 cases of perforating ulcer of the appendix Kelly[4] states that To Thomas G Morton of Philadelphia, belongs the credit for the first successful removal of the appendix deliberately undertaken That was on April 27 1887 After this time the names of Ochsner Murphy McBurney and Deaver stand out as proponents of the surgical removal of the appendix and they did much to increase the knowledge of appendicitis and its treatment

Anatomy —In fetal life the appendix is a prolongation of the conical cecum As the cecum develops the lateral side grows more rapidly so that the appendix in the adult type of cecum comes off its medial wall about 2 cm below the entrance of the ileum The three longitudinal folds of the cecum converge at the appendix and are continued on it

The appendiceal mesentery arises from the under layer of the mesentery of the ileum and usually extends to the tip of the appendix It is however shorter than the appendix, a relationship which when exaggerated, accounts for unusual curving kinking or even spiraling of the appendix The appendiceal artery runs within the mesentery One of the most significant anatomical factors in disease of this viscus is that the appendiceal artery is a terminal vessel without anastomosis

The normal position of the cecum is in the right iliac fossa so here the base of the appendix is usually found (Figs 73 and 74) *The appendix itself may be found pointing* in any direction from this point (Fig 75) It may lie horizontally or may be directed into the pelvis or be directed upward behind the cecum—retrocecal appendix—or laterally The most frequent position is behind the ileocecal junction The retrocecal position is next most frequent In children the appendix is most frequently found directed into the pelvis

Etiology —Since the appendix is a blind tube the contents of which are discharged by peristalsis into the cecum mechanical factors may play a part in predisposing to infection The contents are of course heavily laden with bacteria particularly those of the colon group When the cecal outlet is blocked by fecal material stricture or a concretion a train of events is started which was described in the classic paper by Van Zwalenburg[5] in 1905 The efferent vessels which are within the resisting wall of the appendix *will be more or less occluded* by the greater pressure in the cavity Every atom of fluid which remains within the wall of the cavity adds its pressure to that already present and causes greater obstruction to the efferent current now if this occurred in perfectly sterile surroundings this balance might be maintained for some time without material harm enough fluid would filter through to maintain life in the cell But our cavity is far from sterile

With the circulation empeded the tissue cells deprived of their supply of food and oxygen offer little resistance to the attack of germs Wangensteen and his associates[6] many years later confirmed and extended these observations on the obstructive

mechanism in acute appendicitis To this etiological factor must be added the strepto coccal infections which are so frequent and which rise in frequency when acute res piratory infections are prevalent These two factors may act simultaneously

Symptoms —The classical symptomat ology of appendicitis is that of pain tender ness and rigidity in the right iliac fossa The symptoms vary according to the location of the appendix the extent of the disease and the individual reaction of the patient Nau sea and vomiting are usual but not con stant symptoms The temperature is usually

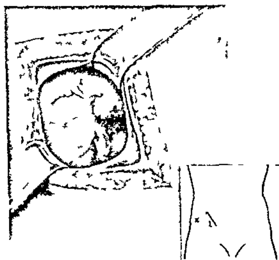

Fig 73 —Exposure afforded by the McBurney in cision Frequently no small bowel is seen except the terminal ileum

elevated but may remain normal for some hours following the onset of pain

Pain —In acute appendicitis pain is al most without exception the first symptom It most frequently comes on suddenly and is at first paroxysmal in character The first pain may develop around the umbilicus or in the epigastrium and later localize in the right iliac fossa but it must be emphasized that the later localization of the pain will depend upon the position of the appendix

Rarely acute appendicitis is present with little or no pain A history of nausea and tenderness upon pressure is however usu ally obtained When intense pain suddenly disappears perforation or gangrene of the appendix must be suspected This is the pe riod that DaCosta[7] called the calm before the storm Sometimes a constant dull pain

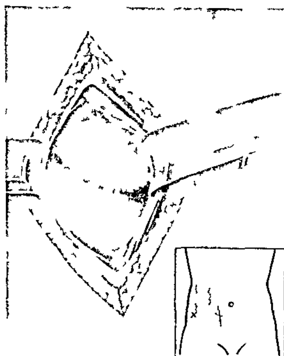

Fig 74 —Exposure afforded by a lower right rec tus incision Two loops of small bowel present in the wound. The author regards this as a definite disad vantage when a severely diseased appendix is to be removed because this area may be contaminated need lessly

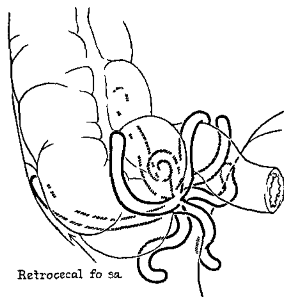

Fig 75 —Diagram showing some of the positions in which the appendix is frequently found

develops gradually in intensity This is rare in children but not uncommon in older pa tients

The first paroxysmal crampy pain may be due to distention of the appendix and is often associated with the presence of a fecalith The later, more constant pain is due to the involvement of the visceral and parietal peritoneum and is then dependent on the location and relations of the appendix As peritonitis extends the tenderness spreads with the process When an abscess develops the tenderness becomes localized Occasionally with an appendix which lies in the pelvis tenderness may be elicited only on rectal examination

When the disease is limited to the appendix tenderness may be slight but may be increased if pressure on the abdominal wall is suddenly released This sign rebound tenderness is a valuable aid in diagnosis when signs of the disease are not well defined

Rigidity—This reflex protection of the peritoneum which must be distinguished from voluntary rigidity varies according to the degree of pain and the extent of peritoneal involvement When present it is one of the most reliable signs of acute appendiceal disease although the degree of rigidity may vary widely in patients with a similar involvement of the appendix If the appendix lies low in the pelvis or if it is retrocecal the rigidity may be slight If the diseased appendix lies in contact with the peritoneum of the anterior abdominal wall the rigidity may be marked from the beginning With the spread of the infection to the peritoneum localized or even generalized board like rigidity may be present

Delicate palpation will elicit this sign much more accurately than deep pressure

Fever—There is nearly constantly some elevation of the temperature in acute appendicitis but this may be slight It is not uncommon to find the fever only 99° or 99 4° F but it may be as high as 103° F or higher This is true in the acutely obstructed appendices with infection and following perforation The fever is more apt to be low than high Chills are rare in uncomplicated appendicitis but are relatively frequent when the vascular supply to the appendix becomes involved

Leukocytosis—Leukocytosis of some degree is to be expected This varies greatly but as a rule a count of over 20 000 cells per cu mm raises a question as to the diagnosis or strongly suggests perforation Ten thousand or over should be considered as suggestive in the presence of other symptoms and signs of appendicitis In children the leukocyte count is frequently higher than in the adult Polymorphonuclear leukocytosis may be present with a practically normal total white cell count

Nausea and vomiting are frequently present but may be entirely absent In children vomiting may be the first evidence of appendicitis

Differential Diagnosis—The differential diagnosis is influenced by age and sex

In the child fever and abdominal pain may be due to a *gastro intestinal disturbance* in which colic is present but localized rigidity and tenderness are usually absent

Pneumonia with referred pain from diaphragmatic irritation may simulate appendicitis and presents one of the most difficult problems in differential diagnosis Rapid respiration and absence of rebound tenderness aid in the diagnosis but the most valuable sign is absence of tenderness or a mass on rectal examination *Lymphadenitis* of the mesenteric glands presents a real problem in diagnosis especially in the first attack A more gradual onset a low leukocyte count and more general tenderness lead one to suspect this condition but accurate differential diagnosis is often difficult and at times impossible

After puberty in the female a *ruptured graafian follicle* may be impossible to differentiate from appendicitis If the hemorrhage is extensive there may be faintness A normal temperature a high leukocyte count and the occurrence of the pain at the mid period of the menstrual cycle are suggestive However this diagnosis is usually made after the abdomen is opened *Torsion of an ovarian cyst* is also a diagnosis that is difficult to make before operation unless the cyst is large enough to be felt on rectal or vaginal examination

A ruptured tubal pregnancy may as a rule be diagnosed from the history of missed menstruation by the signs of intra abdominal hemorrhage by localized tenderness on vaginal examination and a history of some vaginal bleeding Since this is also a surgical lesion the diagnosis is of importance mainly

because of the selection of the type of incision to be used

Acute salpingitis with right sided pain may be differentiated by the history of burning on voiding and a vaginal examination which will show a cervical discharge and localized tenderness in the pelvis The sedimentation rate is greatly increased The signs will usually be more pronounced than the general illness of the patient In infection of a pelvic appendix giving as many signs and symptoms the patient is usually acutely ill

Acute cholecystitis may offer a problem for a high lying appendix and a low lying gallbladder may give tenderness in nearly the same region In acute cholecystitis however the tenderness will be located along the lower border of the liver and often the gallbladder can be felt The reference of pain in gallbladder disease is usually to the back and right shoulder If the patient is not seen before there are signs of abscess formation the surgeon must make the decision as to the optimal time for operation and whether the appendix should be removed at the time the abscess is drained

Diverticulitis of the colon usually occurs on the left side and the onset of symptoms is more gradual However a *ruptured diverticulum* of the ascending or even descending colon and a ruptured appendix may have identical symptoms

Ureteral stone and *infection of the right kidney* may give symptoms referred to the right lower quadrant but the tenderness in kidney infection will be felt when the kidney is palpated and the urine will as a rule contain blood or pus The initial pain begins as a rule in the back and radiates to the suprapubic area However an acutely inflamed appendix lying over the ureter may give rise to all of the symptoms so that it seems better to operate for rarely does the patient in whom the diagnosis is incorrect die following operation but if one waits until peritonitis more accurately leads to the diagnosis the mortality must remain high

Treatment —The treatment of acute appendicitis is surgical removal of the appendix as early in the disease as possible If the patient is not seen before there are signs of abscess formation the surgeon must make the decision as to the optimal time for operation and whether the appendix should be removed at the time the abscess is drained There is no medical treatment for acute inflammation of this viscus It is of course of first importance that if appendicitis is suspected nothing be given by mouth until the diagnosis is certain Laxatives should never be given if there is any possibility of appendiceal involvement because of the danger of perforation

Prognosis —The prognosis depends upon the extent of the infection at the time of operation and it is for this reason that prompt diagnosis is of such importance When the infection is limited to the appendix there should be practically no mortality from this operation The mortality is proportional to the extent of the spreading infection and it must be remembered that perforation is not necessary for the presence of peritonitis The rapid spread of peritoneal infection usually indicates perforation near the base of the appendix Careful postoperative treatment has done more to reduce the mortality in appendicitis with peritonitis than any change in operative technic In acute suppurative appendicitis the use of sulfonamides locally and parenterally has reduced the mortality in a number of clinics by more than 50 per cent Sulfonamide therapy does not take the place of sound surgical principles in the care of these patients

Chronic Appendicitis —This is a term which has in recent years been used less and less frequently since the process to which it should refer is not a continuous low grade infection but recurrent attacks of infection with residual scarring and adhesions Vague constant or burning pain in the right iliac fossa will seldom if ever be relieved by appendectomy If a patient has a history of repeated attacks of pain in the right lower quadrant with fever and nausea and vomiting during the attacks the diagnosis of recurrent appendicitis must be considered and if other causes for the pain can be eliminated the appendix should be removed during the attack or in the interval between attacks The appendix in these cases may be found firmly bound down by adhesions or attached to other viscera such as the ileum fallopian tube or ovary the ureter or even to the under surface of the liver

Appendicitis in Children—The cardinal symptoms of appendicitis are similar in the child and adult but are more difficult to elicit in the child because of lack of intelligent cooperation The signs also may be obscure in a crying infant Frequently in a child the first symptom that is noticed is vomiting and refusal of food Since a young child may have such symptoms from dietary indiscretions all too frequently the parents have given a cathartic before consulting a physician A careful examination will elicit the signs of rigidity and tenderness the tenderness frequently being found only on rectal examination The fundamental difference in the progression of the disease in infants and children is due to the late development of the omentum In the child the short omentum cannot as effectively wall-off a perforation and confine the infection to the ileocecal region as can the fully developed adult omentum The pelvic appendix is less easily walled off and here too the child is at a disadvantage

The etiology of appendicitis in children is the same as in adults but with the addition of occasional cases due to the oxyuris

Acute infection of the mesenteric lymph glands is especially frequent in childhood Slight or even moderate fever and pain may be present The differential diagnosis is important but the absence of localized tenderness and the more generalized pain in lymphadenitis often aid in making this It is better to operate on a case of lymphadenitis than to fail to operate on a case of acute appendicitis Under the age of two while the disease is relatively uncommon the mortality is very much higher than in the adult

INTESTINAL OBSTRUCTION

Definition—Intestinal obstruction or ileus may be defined as a diminution absence or reversal of the normal flow of the intestinal contents due to partial or complete occlusion or to inadequate propulsion Whereas in common usage the term usually signifies an actual mechanical hindrance to progression of intestinal contents it should be realized that this is a restricted conception and that the condition may also be produced by disturbances of intestinal motility resulting from nervous or vascular influences

Etiology—Undoubtedly the largest number of cases of intestinal obstruction are caused by mechanical agents which actually interfere with forward motion of the intestinal contents This may be produced by various factors which can act by actually plugging the lumen constricting the tube or compressing it from the outside Accordingly the various factors which may produce mechanical obstruction can be classified into three types (1) intraluminal (2) mural and (3) extramural Examples of the first type which has been referred to as obturation are foreign bodies gallstones bezoars enteroliths and worms The mural type is typified by hernia volvulus and compressive tumors Ileus may also be produced by certain functional nervous disturbances resulting in peristaltic failure Ileus may be classified into two types (1) adynamic (inhibitive or paralytic) ileus and (2) dynamic (spastic) ileus Failure of peristalsis may also be produced by vascular insufficiency in which the musculature of the bowel loses its capacity for contractile response This is exemplified by mesenteric thrombosis and embolism The following classification of intestinal obstruction is based upon these conceptions

Etiology

I Mechanical Obstruction
- A Intraluminal
  - Obturation
    - Foreign bodies gallstones enteroliths worms inspissated feces and barium
- B Mural
  - 1 Congenital atresia
  - 2 Imperforate anus
  - 3 Strictures
  - 4 Adhesions
  - 5 Intussusception
  - 6 Neoplasms
- C Extramural
  - 1 Hernia
  - 2 Volvulus
  - 3 Compression

II Functional Obstruction
- A Adynamic (inhibitive or paralytic) ileus
- B Dynamic (spastic) ileus

III Vascular Obstruction
- A Mesenteric thrombosis
- B Embolus and infarction
- C Hemorrhage

It should be realized that although intestinal obstruction may be produced independently by any one of these three principal mechanisms *i e* mechanical functional or vascular it is possible and not infrequent that one becomes superimposed upon the other and that they even act concurrently Moreover the initial operation of one factor may not be sufficient to produce complete obstruction but the additional effect of one or both of the other factors is enough to eventuate occlusion Thus the original cause of obstruction may be an adynamic ileus following operation If adequately treated early this may be of no consequence but if the distention is allowed to progress a segment of bowel may become twisted and produce actual mechanical occlusion of the lumen or the distention may be sufficiently extensive to produce circulatory embarrassment in the wall of the involved lumen Similarly in hernia the lumen of the involved segment may be only partially occluded but sufficiently to hinder the propulsion of the intestinal contents The resultant stasis and dilation cause interference with venous return thus increasing the edema of the bowel wall this further augments the constriction resulting in complete occlusion and even strangulation Hence partial mechanical occlusion becomes converted into complete obstruction by the addition of the vascular factor

Special Types of Obstruction —*Obturation Ileus* —Obturation ileus may be defined as that form of ileus in which a mechanical obstruction is caused by intraluminal agents These may be of different types such as gallstones intestinal parasites fecaliths enteroliths concretions bezoars food boli miscellaneous foreign bodies meconium and epithelial casts This type is rare comprising about 2 per cent or less of all types of ileus

In addition to normal feces which under abnormal conditions such as Hirschsprung s disease may become inspissated and impacted the accumulation of excessive amounts of vegetable material resulting from ingestion of various indigestible substances such as celery fibers skin stems and seeds can produce obstruction Also the imbibition by painters or furniture workers of furniture polish because of its high alcoholic content may result in the deposition of concretions consisting principally of shellac

In the case of gallstone ileus the stone is usually quite large and gains entrance into the gastro-intestinal tract by passing directly from the fundus of the gallbladder into the duodenum by erosion and the production of a cholecystoduodenal fistula In most instances of obturation ileus the obstruction occurs in the distal ileum because this is the narrowest part of the small bowel In obturation ileus there is a great likelihood of erosion occurring because of the pressure necrosis which is produced by the hard foreign body

Congenital Atresia —By congenital atresia is meant an absence of the lumen due to some failure or arrest in the normal embryologic development of the intestinal tract The condition appears about once in every 20 000 births The condition is frequently associated with other congenital anomalies such as heart disease cystic kidneys and malformations of the extremities The lower ileum is the most frequent site of involvement Multiple areas are present in about 15 per cent of cases The degree of involvement varies from stenosis or narrowing of the lumen to complete occlusion

Imperforate Anus —Imperforate anus and atresia of the lower portion of the rectum occur about once in 5000 births with equal

  C Hemorrhage

It should be realized that although intestinal obstruction may be produced independently by any one of these three principal mechanisms *i e* mechanical functional or vascular it is possible and not infrequent that one becomes superimposed upon the other and that they even act concurrently Moreover the initial operation of one factor may not be sufficient to produce complete obstruction but the additional effect of one or both of the other factors is enough to eventuate occlusion Thus the original cause of obstruction may be an adynamic ileus following operation If adequately treated early this may be of no consequence but if the distention is allowed to progress a segment of bowel may become twisted and produce actual mechanical occlusion of the lumen or the distention may be sufficiently extensive to produce circulatory embarrassment in the wall of the involved lumen Similarly in hernia the lumen of the involved segment may be only partially occluded but sufficiently to hinder the propulsion of the intestinal contents The resultant stasis and dilation cause interference with venous return thus increasing the edema of the bowel wall this further augments the constriction resulting in complete occlusion and even strangulation Hence partial mechanical occlusion becomes converted into complete obstruction by the addition of the vascular factor

Special Types of Obstruction.—*Obturation Ileus*—Obturation ileus may be defined as that form of ileus in which a mechanical obstruction is caused by intraluminal agents These may be of different types such as gallstones intestinal parasites fecaliths enteroliths concretions bezoars food boli miscellaneous foreign bodies meconium and epithelial casts This type is rare comprising about 2 per cent or less of all types of ileus

In addition to normal feces which under abnormal conditions such as Hirschsprung s disease may become inspissated and impacted the accumulation of excessive amounts of vegetable material resulting from ingestion of various indigestible substances such as celery fibers skin stems and seeds can produce obstruction Also the imbibition by painters or furniture workers of furniture polish because of its high alcoholic content may result in the deposition of concretions consisting principally of shellac

In the case of gallstone ileus the stone is usually quite large and gains entrance into the gastro intestinal tract by passing directly from the fundus of the gallbladder into the duodenum by erosion and the production of a cholecystoduodenal fistula In most instances of obturation ileus the obstruction occurs in the distal ileum because this is the narrowest part of the small bowel In obturation ileus there is a great likelihood of erosion occurring because of the pressure necrosis which is produced by the hard foreign body

Congenital Atresia—By congenital atresia is meant an absence of the lumen due to some failure or arrest in the normal embryologic development of the intestinal tract The condition appears about once in every 20 000 births The condition is frequently associated with other congenital anomalies such as heart disease cystic kidneys and malformations of the extremities The lower ileum is the most frequent site of involvement Multiple areas are present in about 15 per cent of cases The degree of involvement varies from stenosis or narrowing of the lumen to complete occlusion

Imperforate Anus—Imperforate anus and atresia of the lower portion of the rectum occur about once in 5000 births with equal

sex incidence The condition may be explained on the basis of arrests or abnormalities of embryologic development of the post-allantoic gut Failure of closure of the cloacal duct results in fistulous communication between the rectum and genito urinary apparatus Accordingly, two types of imperforation are observed (1) simple imperforation, and (2) those imperforations associated with fistulous communications which are usually rectoperineal or in the male rectovesical and recto urethral and in the female rectovaginal The character of the obstruction varies from stenosis to atresia with the rectum terminating as a blind sac for variable distances above the perineum

Strictures —Intestinal obstruction may be produced by strictures which narrow or occlude the lumen These strictures may be congenital or acquired benign or malignant The acquired cicatricial forms may follow mechanical or operative trauma vascular injury such as infarction or bacterial or inflammatory reactions As a cause of intestinal obstruction they are relatively rare

Any form of bowel ulceration with subsequent cicatricial healing may result in sufficient narrowing of the lumen to produce obstruction Of these regional enteritis which is frequently multiple, is one of the most common Other forms of ulcerative processes are those associated with tuberculosis bacillary dysentery ulcerative colitis and typhoid fever Diverticulitis especially of the sigmoid and occurring usually in older patients may produce sufficient inflammatory reaction to cause obstruction Rectal strictures are most commonly produced by granulomatous processes such as syphilis and lymphogranuloma inguinale

Trauma incident to intra abdominal operative procedures and faulty anastomoses may cause stricture formation Accidental trauma also may give rise to the condition by vascular injury of the mesenteric vessels and production of hematoma or infarction Traumatic stricture may also follow reduction of strangulated hernia especially the femoral type Irradiation therapy for pelvic malignancies has been known to produce obstruction by stricture formation

The pathologic features are those of mechanical obstruction and the type of lesion producing the occlusion Regional enteritis strictures are frequently multiple and most commonly involve the lower ileum and cecum In ulcerative colitis and amebic lesions the strictures involve varying lengths of the colon In granulomatous lesions which most frequently concern the rectum the degree of involvement may vary from ring-like constriction to contraction of the entire rectum In practically all forms the degree of obstruction may vary from simple narrowing to almost complete occlusion The obstruction is almost invariably of the simple type and strangulation rarely complicates the condition

Adhesions Ileus —Adhesions are responsible for approximately a third of all cases of intestinal obstruction and the majority of these follow intra abdominal operative procedures or infections Of the operations appendectomy is the most frequent and gynecologic procedures are next Drainage of the peritoneum is believed to increase the liability The pathogenesis of these adhesions is not thoroughly understood Fibrinous peritoneal adhesions normally occur as a localizing protective mechanism to various forms of mechanical clinical or bacterial trauma Once this process has served its usefulness the fibrinous adhesions are normally digested by proteolytic ferments In some cases, however they become organized and replaced by fibrous adhesions In addition to postoperative adhesions ileus may be produced by congenital bands and adhesions such as the avascular fold between the terminal ileum and cecum adhesions which follow endometrial transplants tuberculous peritonitis and other non-operative peritoneal infections The mechanism of adhesions ileus varies but is usually due to kinking traction torsion or actual compression The presence of Meckel s diverticulum may initiate an obstruction by these various processes

Intussusception —Intussusception may be defined as the invagination of one portion of the intestine (the intussusceptum) into usually an adjacent, more distal segment (the intussuscipiens) This is the descending type the ascending or retrograde type is rarely observed Intussusception comprises about 5 per cent of all cases of intestinal obstruction and is the most common cause in children Approximately 75 per cent of

the cases occur in children less than two years of age and 50 per cent in those less than one year The ratio of males to females is about two to one Various causative factors have been cited but in infants in whom the condition is most common there is usually no apparent cause According to some observers the pathogenesis may be explained on the basis of irritation of the mucous membrane by varying agents particularly strong cathartics structural peculiarities which permit excessive mobility dysfunction of nervous control or incoordination and the presence of excessive lymphoid tissue about the ileocecal valve and terminal ileum Other etiologic factors particularly in adults include the presence of Meckel s diverticulum pedunculated tumors carcinoma inflammatory lesions and foreign bodies

FOUR TYPES of intussusception have been recognized (1) *enteric*—entirely within the small intestine (2) *ileocecal*—the ileocecal valve forming the apex of the invaginated bowel (3) *ileocolic*—invagination primarily of the ileum through the ileocecal valve and (4) *colic*—entirely within the colon The ileocecal and the ileocolic types are the most common Whereas usually there is no actual occlusion of the lumen in intussusception the obstruction is due to the active contraction of the sheath particularly at the neck In addition to this because of the tension of the mesentery of the intussusceptum and its compression vascular disturbances are liable to occur early Accordingly the greatest pathologic changes are found in the intussusceptum which soon becomes edematous indurated and engorged with blood There is excessive mucous secretion extravasation of blood into the lumen and eventually especially in the irreducible form ulceration gangrene and perforation

Neoplasms—Exclusive of hernias as a cause of intestinal obstruction neoplasms comprise about one sixth of the cases and are among the most frequent causes in patients past middle life These include benign and malignant tumors the former arising most frequently in the small bowel and the latter in the colon Lipoma fibroma adenoma and angioma comprise the benign tumors The malignant tumors include primary and metastatic carcinoma and sarcoma Primary carcinoma is by far the most frequent type of lesion and most commonly involves the colon *Carcinoid tumors* frequently referred to as argentaffinomas usually occur in the appendix and lower ileum and give rise to obstruction Whereas carcinoma situated in any part of the large bowel may produce obstruction it is more liable to occur in the left half and approximately half of the cases are in the sigmoid Metastatic carcinoma may produce intestinal obstruction by contiguous growth usually from primary lesions arising in the pelvic adnexa by distant implantation and involvement of neighboring loops or by lymphatic extension and eventual encirclement of the bowel Occasionally in both benign and malignant tumors the obstruction is precipitated by the development of intussusception especially in the presence of polypoid growths Volvulus may also occur Inflammatory swelling and edema are particularly important factors in precipitating acute obstruction in carcinoma of the large bowel

The pathologic features are those of mechanical obstruction and of the type of neoplasm concerned In cases in which chronic obstruction has preceded the acute attack there may be hypertrophy and edema of the bowel wall above the site of obstruction Because of the mechanism of the ileocecal valve in preventing regurgitation colonic obstructions are converted into closed loops with consequent circulatory embarrassment or strangulation Accordingly gangrene and perforation are more liable to occur in these forms Perforation may also be due to the malignant process

Hernia—External hernias are by far the most frequent cause of intestinal obstruction comprising almost 50 per cent of the cases A much smaller number is caused by internal hernias Inguinal hernias are the most frequent cau e of intestinal obstruction and of the hernial obstructions the next most frequent are femoral umbilical and incisional Hernias are of importance in the production of ileus not only because of the mechanical obstruction offered by the presence of an intestinal loop in the hernia and compression at the neck but also because of the liability of early vascular interference consequent to compression of the vessels in the mesentery In addition to compression of

the intestinal loop at the hernial orifice, an increased accumulation of gas and fluid in the imprisoned loop tends to produce an intramural strangulation In some instances the herniated loop of bowel may become adherent to the hernial sac and hence irreducible This is less likely to be associated with an acute obstruction than is the case in which the hernial orifice is relatively small and in which the loop is readily reduced

The distention of the herniated loop of bowel is caused by the accumulation of gas and fluid forced into the isolated loop by the propulsive power of the intestine and to the relative inability of the herniated loop to evacuate them through the compressed distal loop It is for this reason that rigid hernial rings are more liable to produce intestinal obstruction and strangulation than those in which the orifice is more pliable Intestinal obstruction associated with external hernias are more readily recognized than those associated with internal hernias because of their obvious presence In cases where there is vascular interference (strangulation) varying degrees of color change are observed in the bowel from cyanosis to the greenish black discoloration of actual gangrene

Volvulus —By volvulus is meant torsion or twisting of a segment of bowel on its mesenteric axis usually in a clockwise direction Volvulus comprises about 10 per cent of all cases of intestinal obstruction It is usually due to increased length or defective fixation of the mesentery permitting abnormal mobility of the attached loop of bowel Coarse vegetable diets on an empty gastro intestinal tract violent catharsis or other stimulation of overactive peristalsis unusual physical exertion or other traumas such as falls or jumps have been considered as precipitating factors The ileocecal area and sigmoid are the most frequent sites of involvement the former being more common in children and the latter in adults Its incidence is slightly greater in males As a result of the torsion and consequent compression of the mesenteric vessels especially the veins circulatory disturbances occur early Venous engorgement develops first and hemorrhagic infarction finally occurs The involved segment of bowel becomes edematous discolored and eventually gangrenous and perforated The distended loop due to extravasation usually contains more fluid than gas There may be evidence of localized peritonitis and free peritoneal fluid

Functional Obstruction —Functional obstruction may be defined as failure of normal propulsive peristalsis resulting from a disturbance in the nervous mechanism or contractile response This type of intestinal obstruction may be classified into two forms (1) adynamic (inhibition paralytic) ileus, and (2) dynamic (spastic) ileus

A mild form of ADYNAMIC ILEUS occurs following almost all intra abdominal operations and is probably due to splanchnic irritation This moderate degree of intestinal paresis is manifested by slight distention and inability to expel gas and the subsequent gas pains indicate the return of peristaltic activity Whereas adynamic ileus is observed most frequently following peritonitis and other intra abdominal lesions such as strangulation of the omentum, renal and biliary colic torsion of an ovarian cyst, retroperitoneal hematoma and infections it may also occur following extra abdominal lesions and systemic infections It has been observed following fractured ribs or other bones spine injuries and blunt trauma to the abdomen Pneumonia typhoid fever meningitis and other infectious diseases may be associated with severe adynamic ileus Embolism and thrombosis of the mesenteric vessels also produce this type of obstruction and it may be superimposed upon or follow mechanical ileus In these conditions there is the additional factor of circulatory embarrassment which by interference with the blood supply of the intestinal musculature further reduces its capacity for contractile response The common conception that in this condition the intestinal wall is paralyzed is erroneous for it has been repeatedly demonstrated experimentally and clinically that following interruption of sympathetic impulses by splanchnic block or spinal analgesia the ability of the intestinal musculature to contract is normal Most observers believe that the condition is due to hyperactive sympathetic influence Accordingly the term "reflex inhibition ileus is more accurately descriptive than paralytic ileus The dilatation which may vary in degree from mod

erate to extreme usually involves the entire intestine and the bowel wall appears thin and dusky Clinically the condition is characterized by pronounced meteorism due mostly to swallowed air and in contradistinction to mechanical obstruction colicky pain is absent Moderate tenderness may be present and auscultation reveals a relatively silent abdomen In contradistinction to the mechanical forms of ileus these patients characteristically appear euphoric and exhibit less anxiety

DYNAMIC OR SPASTIC ILEUS is rare and in contrast to adynamic ileus is characterized by actual spastic contraction of a segment *of the bowel usually the colon Various* causative factors have been observed including lead poisoning injuries irritating intraluminal contents or mural lesions such as foreign bodies intestinal worms ulcers tuberculous peritonitis neurasthenia and hysteria renal colic and infectious fevers Cases have also been observed in which there is a combination of dynamic and adynamic ileus The condition is believed to be due to disturbances arising in the intrinsic nervous mechanism of the bowel wall The pathologic features consist of constriction and thickening of a segment of bowel with occasional ring like contractions The bowel above the collapsed segment is dilated with an accumulation of fluid and gas Gangrene and perforation do not occur Clinically the condition closely simulates mechanical obstruction and neurotic tendencies frequently may be detected

Vascular Obstruction—Vascular obstruction usually results from interference with the blood supply to a segment of bowel This is most commonly caused by occlusion of the mesenteric vessels Arterial occlusion due to thrombosis and embolism is slightly more frequent than venous and affects the superior mesenteric artery more frequently than the inferior Venous thrombosis is usually due to infection especially of the portal radicals Other initiating agents are strangulation trauma and prolonged alcoholic bouts The pathologic features consist essentially of edema distention discoloration with transudation of serosanguineous fluid into the lumen and the peritoneal cavity gangrene and eventual perforation of the infarcted segment The usual clinical manifestations consist of sudden acute abdominal pain, shock vomiting diarrhea and melena

Pathologicophysiologic Changes in Ileus—In acute intestinal obstruction especially if the obstructing lesion is located high in the intestine there occur certain characteristic biochemical changes consisting essentially of dehydration hypochloremia alkalosis hemoconcentration increased nonprotein nitrogen and urea and possibly hypopotassemia Most of these at least the dehydration dechlorination alkalosis and hemoconcentration can be explained on the basis of loss of fluid and electrolytes from the upper intestinal tract Normally the *upper portions of the alimentary tract* are secretory and the lower are absorptive It has been estimated that about 7000 cc of fluids consisting of gastric secretions succus entericus bile and pancreatic juice are poured into the gastric and upper intestinal tract daily and under normal conditions most of this is absorbed in the lower portions of the intestine If there is an interference with the normal transportation of these large quantities of fluid stagnation and dilatation occur in the upper intestinal tract with consequent nausea and vomiting and loss of these fluids The loss of these fluids and electrolytes (the sodium and chloride ions) is largely responsible for dehydration The alkalosis may be explained on the basis of the loss of the acid radical chloride Normally the sum of the basic ions in the plasma must equal that of the acid ions sodium comprises the greater part of the former and chloride the latter The body s attempt to maintain this equivalence in the presence of relative deficiencies of one or the other of these ions is based upon the adjustability of the bicarbonate ion In the gastric juice there is a greater amount of chloride ion and in the bile and pancreatic juice a larger quantity of sodium ion In high intestinal obstruction there is a greater loss of chloride ion (because the vomitus contains a greater amount of gastric juice [and hydrochloric acid]) than sodium ion and the relative excess of the basic ions principally sodium is compensated by an increase in bicarbonate ion with resultant alkalosis The hemoconcentration which is observed particularly in high intestinal obstruction may be due in part to the dehydration fol

lowing the loss of fluids but also in part to the loss of plasma into the lumen and the wall of the involved intestine

In addition to the above biochemical changes practically all cases of ileus show a gradual accumulation of gas and fluid proximal to the obstruction which produces distention of the bowel The gas in the dilated loops of bowel is to a large extent (about 70 per cent) due to swallowed air

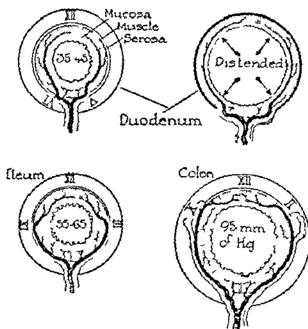

Fig 76—Diagrammatic illustration of relative position of intramural vessels and resultant effects of increased intra-enteric pressure in various parts of intestinal tract If cross section of bowel is represented by the face of a clock with mesenteric attachment at six o clock the vasa rectae pierce the muscularis in the case of the duodenum at approximately five and seven o clock in the jejunum and ileum at nine and three o clock, and the colon at two and ten o clock Thus in the duodenum any increase in intra intestinal pressure results in considerable compression of the relatively long vessels which lie between the mucosa and the muscularis whereas in the colon because the greater portion of the vessels lies outside the muscularis an increase in the intra intestinal pressure exerts little effect on the blood supply

Another possible source of the increased amount of gas is that derived from putrefaction of food and disturbances in gaseous interchange A large portion of the gas in a distended loop of bowel is nitrogen possibly due to the fact that it is less readily absorbed than other gases Similarly the fluid accumulation is an important factor in producing dilatation This is partly due to the failure of propulsion of intestinal fluids from the secretory portion of the gastro-intestinal tract into the lower absorptive areas

The *symptoms* and *prognosis* in acute ileus are largely dependent upon the viability of the bowel wall In those cases in which there is an interference with the blood supply to the intestine the patient is much sicker appears much more toxic and is more liable to die early than is the patient without strangulation Also everything else being equal the higher the obstruction the worse the prognosis and the more rapidly progressive the course Whereas many are of the opinion that in high intestinal obstruction the progressive deterioration of the patient is due to the excessive loss of fluids and electrolytes there are others who believe that in these instances the early interference with the blood supply by compression of the vessels within the wall of the intestine that is an intramural strangulation is the responsible factor Interference with the blood supply may occur either in the mesenteric vessels or within the wall of the gut as a result of increased intra-enteric pressure. That the upper part of the intestinal tract is particularly vulnerable to distention has been shown repeatedly Dragstedt Lang and Millet have shown that there is considerable variation in the intramural blood vessels in different parts of the intestine and that as a result of this anatomic fact pressure within the gut exerts varying influences on the blood supply of the intestine (Fig 76) In instances in which there is an interference with the blood supply whether it be mesenteric or intramural there is transudation of fluid into the lumen and through the wall with transperitoneal absorption of bacteria and other lethal agents Obviously as the intra enteric pressure increases interference with the venous return from the bowel wall increases thus augmenting the capillary hydrostatic pressure and resultant filtration pressure The associated anoxia produces increased capillary permeability and all these factors result in considerable loss of plasma and aggravation of the ileus If distention is permitted to continue long enough and there is sufficient intramural compression actual necrosis of the gut may occur particularly on the antimesenteric surface where perforation is most liable to be found

Symptoms—The symptoms of intestinal obstruction vary and depend upon the degree and site of occlusion In general sudden acute mechanical occlusions located high in the intestinal tract produce more intense and earlier symptoms than other forms Similarly in strangulation the manifestations are more severe than in simple obstruction Whereas such variations exist with the type and extent of obstruction the cardinal manifestations irrespective of the cause are essentially pain vomiting distention and constipation

Pain is usually the first symptom especially in acute mechanical obstruction It is characteristically intermittent and colicky occurring in severe paroxysms with crescendo rises and after being sustained at a maximum intensity for several minutes it ceases abruptly Early the pain may be located at the site of obstruction but is frequently referred to the mid abdomen Between the paroxysms there is little discomfort except in the presence of strangulation These paroxysms are usually more intense and frequent in small than in large bowel obstruction As distention progresses and the contractile response decreases the intensity and paroxysmal character of the pain recede Whereas paroxysms of colicky pain are characteristic of mechanical obstruction there is little or no pain in functional ileus

Vomiting also varies in intensity and character depending upon the type and site of obstruction In general the higher the obstruction the earlier and more severe is the vomiting At first the vomiting is reflex and although this may occur in other acute abdominal conditions the type of vomitus is particularly significant in intestinal obstruction After the stomach has been emptied of a previous meal by reflex vomiting retching may be unproductive or the vomitus may consist only of bile stained gastric juice This is soon followed by the regurgitation of a grayish glairy material characteristic of intestinal contents especially in high obstruction If the obstruction is low however the appearance of this material may be delayed for hours Although at first this material has a faint odor of moldy food later it develops a fecal or stercoraceous odor which is not necessarily an indication of colonic contents for the fecal odor may be due to protein putrefaction occurring in the small bowel Colonic obstruction even when pronounced is frequently associated with little or no vomiting except the initial reflex vomiting This may be explained on the basis of the ileocecal check valve mechanism which is usually competent and permits fluids and gas to enter the colon but prevents their regurgitation

Constipation is an eventual occurrence in all cases of ileus but may not be significant early Immediately after the onset of an acute obstruction there may be one or two spontaneous bowel movements due to emptying of the intestinal tract distal to the obstruction In fact a history of defecation occurring at the same time as or shortly after the onset of pain with no subsequent bowel movements is frequent in acute intestinal obstruction In incomplete obstruction small diarrheic movements also may occur The presence of blood in the stools indicates strangulation blood and mucus intussusception

Chronic intestinal obstruction may be due to many of the conditions which produce the acute type It is most commonly caused by slow growing benign or malignant neoplasms of the bowel which progressively encroach on the lumen inflammatory and granulomatous lesions of the bowel and intrinsic defects in neuromuscular mechanism such as Hirschsprung s disease Characteristically the onset is insidious and the principal manifestation is constipation which becomes progressively worse Resort to laxatives and purgatives which produce temporary relief is frequent but becomes increasingly necessary and progressively less effective Recurrent attacks of abdominal discomfort colicky pain and distention are common In aged individuals fecal impaction is not infrequent The presence of hemorrhoids and blood streaked stools may also be observed

Physical Findings—Although the signs of acute intestinal obstruction are quite typical there is some variation with the stage and site of obstruction At onset the general appearance of the patient reveals no significant changes As the disease progresses towards a more advanced stage and dehydration and other physiologic disturbances have occurred the characteristic anxious expression with pinched facies fast

thready pulse and cold clammy extremities becomes evident In strangulation and in the late stages of other forms of obstruction in which there is vascular insufficiency of the *involved bowel shock may develop* as the result of blood loss

Abdominal *distention which is due to dila*tation of the bowel proximal to the obstruction is also an eventual occurrence in all cases of ileus It is more likely to be pronounced in lower ileal and colonic obstructions but in early, particularly in high obstructions is characteristically absent Although distention eventually becomes generalized with barrel like abdomen it may *be localized at first Thus* in high obstruction the distention may be limited to the upper *abdomen, while in low colonic* obstruction a prominent fulness appears on each side of the abdomen and extends across the abdomen along the course of the large bowel In advanced stages of lower ileal obstruction a characteristic ladder pattern on the abdominal wall representing dilated intestinal loops may be apparent

Visible peristalsis, which usually indicates *hypertrophy of the bowel is more char*acteristic of chronic obstruction but may be present in acute ileus especially in patients with a thin abdominal wall Furthermore abdominal tenderness and rigidity are not prominent features of simple acute obstruction Although there may be some tightening of the abdominal muscles during paroxysmal attacks of pain the abdomen is re*laxed between these attacks Tenderness and* rigidity indicate peritoneal irritation and their presence suggests strangulation and peritonitis consequent to leakage or perforation

Because of its early and constant character, auscultatory evidence of hyperperistalsis is particularly *significant The loud* whirring gurgling sounds can frequently be *heard* readily without a stethoscope However, auscultation with a stethoscope over various parts of the abdomen may be helpful not only in diagnosing an acute ileus but also in locating the obstruction Characteristically in intestinal *obstruction* these sounds (borborygmi) are heard with greatest intensity at the height of the paroxysmal attacks of pain With progress of the ileus the whirring sounds change to tinkling notes In the late stages of obstruction and in adynamic ileus the abdomen is silent

Laboratory Findings—The characteristic alterations in the blood and urine are probably the result of dehydration and loss of chlorides and electrolytes Hemoconcen*tration is usually* present with increased values for hemoglobin, erythrocytes and leukocytes The *blood chlorides* are decreased and the carbon dioxide combining power and nonprotein nitrogen are increased The urine is scanty and albumin and indican may be demonstrable Whereas these findings are characteristic of acute high obstruction, they usually do not appear until about forty eight hours after the onset and may be readily corrected by the administration *of saline solution and other fluids*

Roentgenographic examination is undoubtedly one of the most valuable diagnostic procedures in acute intestinal obstruction A scout film taken with the patient in the prone position will aid in localizing the site of obstruction by revealing gas in the small intestine only in *obstructions of* the small bowel and in the colon with rela*tively little in the small intestine* in obstructions of the large bowel Because the fluid in the various dilated loops of bowel will assume a level with the gas above a skiagram taken with the patient in the upright position will reveal numerous fluid *levels* Contrast substances should not be given by mouth in cases of suspected *intestinal* obstruction but in obstructions of the colon a *barium enema* may be helpful in determining the site of occlusion In gallstone ileus roentgenography is of value not only because the calculus is sometimes opaque and can be visualized but also because the roentgenographic visualization *of gas* in the biliary tract resulting from the cholecystenteric *fistula is pathognomonic*

Prognosis—The prognosis in intestinal obstruction depends upon a number of factors among the most important of which are the type and extent of obstruction integrity of the blood supply and the *time* elapsing between the onset and the institution of therapy *Thus the mortality* in obstructions due to external hernia is *comparatively low* in spite of frequently associated strangulation because the diagnosis can *be made* relatively early and rational therapy *ie*

operation is usually not delayed On the other hand, the mortality in obstructions due to mesenteric thrombosis and embolism is relatively high because the diagnosis is less obvious and necrosis perforation peritonitis and shock are likely to develop earlier

According to reported statistics the total mortality varies from 17 per cent to over 60 per cent In spite of recent intensive clinical and experimental investigations the general mortality is still inexplicably high Three main theories have been advanced to explain the high fatality rate The first and oldest is based upon the concept that a potent toxin is formed in the obstructed intestine and is produced by specific or non specific bacterial growth putrefaction or abnormal mucosal changes or secretions The second theory is based upon the hypothesis that death is due to loss of fluids and electrolytes The third concept that death is related to the element of shock was suggested by the 'shock like manifestations of patients with late acute intestinal obstruction It should be realized that none of the theories is wholly acceptable and that they have been controversial subjects among investigators for many years More recently attention has been directed to the significance of the distention factor and the importance of increased intra enteric pressure in diminishing mesenteric venous absorption

Treatment —Whereas the treatment of acute intestinal obstruction may vary according to the type and degree of obstruction in general the two principal therapeutic objectives consist essentially first in the correction of local and systemic disturbances produced by the obstruction and second removal of the obstructive agent and restoration of normal bowel function

The systemic disturbances which may be pronounced especially in high obstruction consist essentially of dehydration hypochloremia and hemoconcentration These can be combatted by the administration of *saline solution* and *other fluids* as soon as the diagnosis is established Although the loss of electrolytes is a more important factor in high obstruction dehydration plays a significant role in all obstructions The required amount of fluids and saline must therefore be determined in the individual case and will depend upon the site degree and period of obstruction Salt may be administered best in the form of physiologic saline solution and periodic plasma chloride determinations will aid in gauging the salt requirements Determinations of specific gravity of the plasma and the hemoglobin will also indicate the degree of hemoconcentration or dehydration Fluids can be administered in the form of 5 per cent dextrose solution After the initial dehydration and hypochloremia have been combatted adequate hydration can be maintained by the simple method of determining urinary excretion In the presence of normal kidney function sufficient fluids should be administered to permit daily urinary excretion of about 1200 cc

Because the patient often cannot take food by mouth for a number of days *maintenance* of *caloric* and *nitrogen equilibrium* becomes important Accordingly intravenous feedings are necessary The use of 10 per cent or even 20 per cent solution of dextrose administered slowly as an intravenous drip over long periods will aid greatly in meeting the caloric requirements Nitrogen equilibrium may also be sustained by the intravenous administration of amino acids and plasma transfusions Whole blood and especially plasma transfusions are particularly important in cases of vascular obstructions such as mesenteric thrombosis or embolism and in acute mechanical obstructions such as volvulus intussusception and hernias accompanied by strangulation In such cases sufficient blood and plasma loss in the involved segment of bowel may produce serious blood volume reductions eventuating in shock like manifestations Obviously this may be readily combatted by the restoration of normal circulating blood volume with whole blood and plasma transfusions The increasing significance of vitamin requirements has been recently demonstrated In these cases the most important vitamins are B and C which may also be administered intravenously

The significance of distention has been emphasized and is undoubtedly one of the most important of the local factors requiring therapy This may be realized by the fact that in spite of combatting all of the systemic factors mentioned above and the

maintenance of fluid and salt balance, life cannot be sustained long if acute distention of the small intestine remains unrelieved *The significance of decompression* therefore becomes increasingly evident Decompression may be achieved by means of intubation or enterostomy Decompression by intestinal intubation is best accomplished by the use of a double tube or double lumen tube (Miller Abbott) with an inflatable rubber balloon a few inches proximal to a perforated metal tip The tube is inserted through the nose and down the esophagus into the stomach and once the tip is well past the pylorus so that the balloon lies in the duodenum this is inflated and continuous suction applied The inflated balloon stimulates peristalsis by pressure against the intestinal wall and acts as an object of sufficient bulk to permit propulsion downwards Thus as the tube progresses continuous suction removes the accumulated fluid and gas in successive loops of distended bowel and permits decompression and consequent resumption of normal peristalsis which in *turn draws the tube farther downward* This process is continued until the site of obstruction is reached In cases of adynamic (inhibitive) ileus the procedure is also applicable and the mechanism of decompression is similar Whereas this method of decompression is of inestimable value in cases of simple acute mechanical obstruction it should not be attempted in strangulating obstructions or those limited to the colon by a competent ileocecal valve Such cases require early operative intervention Enterostomy which prior to the development of intestinal intubation was commonly employed as a decompressive procedure is now rarely used although it is occasionally justified in certain localized forms of mechanical obstruction

Of great value in the treatment of ileus is the administration of *morphine* or other opium alkaloids Contrary to general conceptions morphine exerts a powerful tonic effect on gut musculature and is helpful in combatting *intestinal distention and its consequent* intramural strangulation both in mechanical and adynamic ileus Extensive investigations have demonstrated that other drugs are of little or no value in ileus

The *inhalation* of a high concentration of *oxygen* has also been found a valuable adjunct in the treatment of intestinal obstruction This is based on the experimental demonstration that the intraluminal pressure produced by gas, especially nitrogen may be appreciably diminished by the inhalation of pure oxygen A possible explanation for this observation is based upon the greater *diffusibility of oxygen and its consequent* replacement of the nitrogen An additional value of this therapeutic procedure lies in the beneficial effect of better and more effective oxygenation in those patients whose respirations are impeded by the pronounced distention and whose respiratory function is diminished by the use of morphine

The second therapeutic objective *ie removal* of the *obstructing agent* and *restoration* of *normal bouel function* must be achieved for complete recovery In the majority of cases surgical intervention is necessary although in some cases of simple mechanical obstruction due to adhesions hernia volvulus or intussusception and also in certain cases of inhibitive ileus the conservative management with decompression and other supportive measures referred to above is sufficient to restore intestinal continuity Conservative decompression should not be prolonged unduly however and if there is no appreciable improvement *in* from twenty four to thirty six hours *operation* should not be delayed Immediate surgical intervention is necessary in strangulating obstructions and acute colonic *occlusions* wi pronounced distention However even i such instances operation should not be at tempted in the presence of considerable de hydration shock or other complications (obstruction which *would* jeopardize th chance of recovery For *this* reason it is de sirable in all cases to improve the patient general condition before operation by uppe gastro intestinal decompression hydration transfusion and other supportive *measures*

Once the decision of surgical interventio has been made the type of procedure indi cated will depend upon the condition foun at *operation* This *in turn is* greatly in fluenced by the viability of the bowel *Thus* in mechanical obstruction due to adhesion or hernia in which after release of the ob struction the bowel is found to be viable Or simple closure *is all that* is necessary

the other hand if the bowel is no longer viable excision of the involved segment with subsequent anastomosis is necessary This may be done by primary resection or by exteriorization of the necrosed portion In some cases especially in the presence of malignant tumors an initial short circuiting procedure or entero anastomosis with subsequent resection may be preferable In certain cases of simple obstruction exploration and removal of the obstructing agent are undesirable and the procedure of choice is the simplest and the least traumatic Under these circumstances an enterostomy or colostomy should be done above the site of occlusion

INTESTINAL NEOPLASMS

Incidence —The intestine is one of the most frequent sites of primary neoplasms about 15 per cent of all cancers arise in the intestines Whereas there is some variation in the relative incidence of different types of tumors in various parts of the gastro intestinal tract in general it may be stated that slightly more than one-half occur in the stomach about two fifths in the colon and rectum and less than one-tenth in the small intestine Of all tumors in the gastro intestinal tract about four fifths are malignant and one fifth benign However this ratio varies in different parts of the alimentary canal Thus although in the stomach about nine-tenths of the tumors are malignant in the colon and rectum about three-fourths are malignant and in the small intestine only slightly more than two-fifths are malignant About 45 per cent of all benign tumors and 37 per cent of all malignant tumors in the gastro intestinal tract are located in the large bowel whereas only about one-fourth of all benign tumors and less than 5 per cent of all malignant tumors are located in the small intestine Of all intestinal (small and large bowel) neoplasms slightly more than four fifths are located in the large bowel and of the malignant tumors almost nine-tenths are in the large bowel

The etiology is unknown but stasis chronic irritation infection embryonic tissue rests and morbid changes in Brunner s glands have been suggested as possible factors The relative infrequency of cancer of the small bowel as compared to other parts of the intestinal tract is significant but no satisfactory explanation has been presented

Small Intestine —*Benign Tumors* —In the small intestine benign tumors are rela

tively more common than malignant neoplasms and tend to occur at younger ages than the latter There is no significant sex incidence Included among the benign tumors are adenoma, lipoma fibroma, myoma hemangioma chylangioma, accessory pancreatic tissue, enterogenous cysts and gas cysts Of these *adenoma* is by far the most common and occurs most frequently in the ileum and next in the duodenum Usually single, they may be multiple and polypoid They vary in size from a few millimeters to several centimeters in diameter Grossly they resemble other polyps and histologically they are characterized by benign hypertrophy and hyperplasia of glandular epithelium of the mucous membrane The potential danger of malignant change in benign adenomatous intestinal polyps should be remembered *Lipomas* are believed to arise from the areolar tissue in the submucosa or subserosa are usually single tend to be pedunculated and are rarely more than a few centimeters in diameter Pure *fibromas* are relatively rare They may be sessile, pedunculated and project into the lumen or externally The tumor appears as a discrete freely movable rather firm mass which microscopically shows connective tissue *Myomas* grossly resemble other benign tumors but histologically are characterized by strands of smooth muscle fibers Hyaline degeneration and hemorrhagic necrosis are common *Hemangioma* and *chylangioma* are extremely rare in the small bowel Chylangiomas are softer more cystic and gray or yellow in color Accessory *pancreatic tissue* or aberrant pancreatic rests are believed to originate as misplaced pancreatic tissue and accordingly are found most frequently in the duodenum and upper jejunum They appear as small irregular rather flattened submucous nodules closely resembling normal pancreatic tissue *Enterogenous cysts* are extremely rare and are believed to arise as a result of some anomaly of embryonic development

The CLINICAL MANIFESTATIONS of benign tumors of the small intestine are variable and depend upon location type and character of the tumor Many never produce symptoms and are recognized accidentally at laparotomy or autopsy Symptoms are usually due to erosion or ulceration and consequent hemorrhage or to intestinal obstruction produced by intussusception or by gradual encroachment on the lumen Tumors in the duodenum usually produce manifestations of progressive obstruction Epigastric pain nausea, vomiting and distention are prominent symptoms Hematemesis and melena are not infrequent As the obstruction increases vomiting and distention become more pronounced Abdominal tenderness is usually present but rigidity is seldom elicited

The DIAGNOSIS is based upon these clinical manifestations and the roentgenologic demonstration of duodenal obstruction or a filling defect representing the tumor In the jejunum and ileum the clinical manifestations are also usually those of obstruction caused by intussusception or gradual occlusion Approximately a fourth of the cases of benign tumors in this segment of the bowel cause obstruction by intussusception and in adults intussusception is most frequently caused by tumors in the ileum In the other forms obstruction is produced by gradual encroachment on the lumen and the symptoms are more insidious The PHYSICAL FINDINGS vary with the stage of the process at first there are few signs except possibly some tenderness and if the tumor is of sufficient size a palpable mass Roentgenologic examination especially with the aid of a double lumen tube passed down to the site of obstruction is of distinct value in the diagnosis

The PROGNOSIS in uncomplicated benign tumors of the small intestine is relatively good Complications such as hemorrhage perforation intussusception, and complete intestinal obstruction increase the gravity of the condition

TREATMENT consists of early and complete surgical extirpation In some cases this necessitates intestinal resection

Malignant Tumors.—Malignant tumors of the small intestine include carcinomas sarcomas and carcinoids or argentaffin tumors Of these carcinoma is probably the most common with sarcoma next in frequency

Carcinoma of the small intestine occurs more frequently in the male sex with the highest incidence in the fourth fifth and sixth decades The duodenum especially the second or periampullary portion is the re-

gion of greatest involvement Several forms of carcinoma of the small intestine are recognized depending upon their gross pathologic or histogenic characteristics Grossly, the most common is the ring type which produces constriction or stenosis Next is the infiltrating ulcerative type which is pearly and firm and has a fibrous appearance The third type is the polypoid form which appears as a fungating mass protruding into the lumen Many believe that these arise as a result of malignant change in a pre-existing benign adenomatous intestinal polyp Histologically these carcinomas are classified into four types adenocarcinoma medullary scirrhous and colloid

The CLINICAL MANIFESTATIONS are variable and depend upon the location size and character of the tumor and the degree of malignancy They are predominantly those of intestinal obstruction A history of abdominal distress and pain is frequent Pain is usually colicky in character and accompanied by nausea and vomiting As the degree of obstruction progresses these attacks increase in frequency and severity Loss of weight and strength and even cachexia are characteristic of malignant growths Tumors of the duodenum may produce hematemesis and melena or symptoms of duodenal ulcer Those located in the periampullary region may produce biliary obstruction and the consequent painless jaundice develops early Malignant tumors of the jejunum and ileum produce symptoms usually of greater intensity but similar to those described for benign tumors in this area with obstruction as the predominant feature When the tumor becomes sufficiently large a movable palpable mass may be present Roentgenography is of diagnostic value especially with the aid of a double lumen tube which can be passed to the site of obstruction

The PROGNOSIS in primary carcinoma of the small intestine is not good Metastasis occurs early and extends first to the regional lymph nodes and peritoneum and then to the liver lungs and other organs

TREATMENT consists of radical resection when the tumor is removable In the non resectable tumors because of extensive metastasis palliative operations for relief of obstruction may be necessary

Sarcoma of the small intestine is about twice as frequent as sarcoma of the large bowel and occurs most commonly in males and in middle aged individuals Depending upon their histogenesis the various forms of sarcomas of the small intestine include lymphosarcoma leiomyosarcoma fibrosarcoma and neurofibrosarcoma Lymphosarcomas comprise two thirds of the cases and leiomyosarcomas about one fourth These tumors especially lymphosarcoma occur most frequently in the ileum and next in the jejunum Lymphosarcoma is believed to originate in a simple lymphoid follicle or in lymphoid tissue located in the submucosa and in the early stage is localized in this region as a soft friable mass It grows by spreading along the tissue spaces and soon infiltrates the muscularis and other tissue layers of the bowel wall This tendency to invasion and destruction of surrounding structures is shown by the cylindrical or rigid tube-like character of the tumor growth Ulceration is late and when it occurs it is characteristically excavated Obstruction may occur as a result of stenosis, intraluminal protrusion or external compression of the tumor intussusception or kinking or by adherence of coils of intestine Metastasis occurs to the regional lymph nodes in the mesentery and especially to the liver Melanosarcoma or malignant melanoma of the small intestine is rare and usually occurs in the rectum It is usually multiple and appears as a polypoid or bosselated tumor with a bluish to black color

Sarcomas of the small intestine produce CLINICAL MANIFESTATIONS which vary from those of acute intestinal obstruction to symptoms of vague abdominal disorders More commonly there is colicky abdominal pain accompanied by nausea and vomiting some fever gradual loss in weight and secondary anemia Occasionally the onset is sudden with manifestations of acute obstruction perforation and severe hemorrhage. Diagnosis is difficult and is based upon the history of colicky abdominal pain loss of weight and strength the presence of secondary anemia and an inconstantly palpable tumor Roentgenologic examination of the small bowel is of value especially with the aid of a double lumen tube which may be passed to the point of obstruction

PROGNOSIS is poor as metastasis is fre-

quent Treatment consists of radical extirpation when this is possible Radiation therapy, especially for the lymphoid type is of some value

Carcinoid tumors, also known as argentaffin tumors because of their affinity for silver dyes are believed to arise from what is known as the chromo argentaffin cells of the normal intestinal mucosa most numerously located in the appendix and terminal ileum and believed in some way related to the chromaffin system These tumors occur most commonly in the ileocecal region with the appendix and especially its tip as the most frequent site Grossly they appear as small rather freely movable nodules varying in size from 0 5 to 1 cm in diameter with a firm somewhat rubbery consistency and a characteristically bright yellow color Lying beneath the mucous membrane they tend to obliterate the lumen of the appendix or bowel Histologically they are characterized by nests or columns of cells surrounded by a stroma of connective tissue and smooth muscle The cells which are fairly regular contain distinctive nuclei and a granular cytoplasm with an affinity for silver They are usually single and commonly regarded as benign but should be considered potentially malignant because about a fifth of the cases show malignant characteristics with considerable enlargement of the original tumor and metastasis to the liver and regional nodes

These tumors appear in either sex and at any age but most commonly in young adults Their CLINICAL FEATURES depend to a great extent upon their location In the appendix the manifestations simulate chronic appendicitis In the small intestine they are symptomless unless they become of sufficient size to obliterate the lumen and then the manifestations are those of intestinal obstruction In the stomach colon and rectum they produce symptoms resembling malignancy The PROGNOSIS is relatively good especially if recognized before metastasis has become widespread Recurrence is rare TREATMENT consists essentially of surgical excision

Colon and Rectum —*Benign tumors* of the colon include epithelial papilloma or adenoma lipoma fibroma myoma myxoma adenomyoma and enterogenous and gas cysts Of these adenoma and lipoma are probably the most common

Adenomas are polypoid tumors which may be sessile or pedunculated single or multiple and limited to one segment of the bowel, or diffuse producing generalized polyposis of the colon The condition appears more commonly in males and in middle or late adult life although the diffuse type which is rarer is encountered more frequently in younger persons Chronic inflammatory lesions of the bowel are believed to be of etiologic significance in the development of these neoplasms According to Erdman and Morris two types of adenomas of the colon may be recognized those known as the adolescent or congenital type which are disseminated and those referred to as the adult or acquired type The former appear as sessile or pedunculated soft round masses of variable size projecting into the lumen and are uniformly distributed in the colon or rectum The latter type is similar in gross appearance but more frequently limited to one segment of the bowel especially the rectosigmoid Histologically they consist of hypertrophic glands on a stalk of connective tissue with a rich vascular supply Whereas both types may undergo malignant change the adult type is more liable to be affected in this manner The potentially malignant character of these adenomatous polyps should be emphasized and many observers believe that all carcinomas of the large bowel arise from polyps

Other benign tumors such as *fibromas lipomas myomas* and *angiomas* may also be polypoid in character They may be sessile or pedunculated single or multiple and are usually symptomless unless they encroach on the lumen or cause intussusception and obstructive symptoms Hemorrhage may be caused by cavernous hemangioma Adenomyoma is due to the implantation of endometrial tissue on the serosal surface of the bowel or the appendices epiploicae As a result of deeper extension into the bowel wall constriction of the intestine may occur

The CLINICAL MANIFESTATIONS of benign tumors of the colon vary with the type of growth and the presence or absence of such complications as hemorrhage intussusception or other obstructive features Solitary pedunculated tumors may produce inter

mittent attacks of localized colicky pain They are a frequent cause of intussusception especially in the adult Adenomatous polypi especially the multiple forms produce more characteristic symptoms There is usually a history of repeated attacks of gastro intestinal upsets with cramp like pain diarrhea hemorrhage from the bowel and the passage of mucus In the diffuse forms the attacks are frequently associated with profuse hemorrhage and secondary anemia However even in the adult type moderate hemorrhage is common Alternating attacks of diarrhea and constipation are not uncommon Progressive loss of weight and anemia are indications of malignant change In cases in which the tumor causes obstruction the symptoms will depend upon the nature and degree of constriction

The DIAGNOSIS of benign tumors of the large bowel is made on the basis of the clinical manifestations and the roentgenologic and proctoscopic findings Solitary tumors that project into the lumen may be demonstrated by roentgenographic studies following the introduction of a radiopaque material Multiple polyposis can usually be demonstrated either by this means or by proctoscopic visualization

The TREATMENT is essentially surgical and consists of excision In cases of obstruction preliminary enterostomy may be necessary Because of their potentially malignant nature polypi should be treated by radical resection of the involved bowel (colectomy) The solitary type with a long pedicle may be excised at the base Polyps limited to the rectum may be treated by fulguration through the proctoscope

Malignant tumors of the large bowel are among the most frequent tumors of the body It is stated (Rankin and Graham) that carcinomas of the colon comprise 15 per cent of all carcinomas In addition to carcinomas other malignant tumors are sarcomas of which lymphosarcoma is by far the most frequent Sarcomas however occur most infrequently In the consideration of tumors of the large bowel it is desirable to differentiate between the proximal and distal halves of the colon because they have different origins different functions and different types of lesions The proximal half of the colon up to the mid portion of the transverse colon is derived from the mid gut and is therefore closely allied to the small bowel The distal portion of the colon that beyond the mid portion of the transverse colon is derived from the hind gut The proximal half is largely absorptive and the distal half is largely for storage The contents of the proximal half are fluid the contents of the distal half are relatively solid Carcinoma involving the right half particularly the cecum is likely to be fungating so-called colloid carcinoma with considerable mucus production whereas those in the distal half are more often of the scirrhous type

The involvement of different portions of the colon varies considerably according to reported statistics According to Henry (Rankin and Graham) the cecum is involved in 15 per cent transverse colon 10 per cent splenic flexure 6 6 descending colon 5 sigmoid 13 rectum and rectosigmoid 56 Of great importance from a diagnostic standpoint in rectal lesions is that approximately 75 per cent of these tumors are within reach of the palpating finger The lesions of the large bowel more frequently affect males than females in a ratio of about two to one

Carcinomas of the large bowel vary considerably in their gross appearance They may be divided generally into three main types (1) a large ulcerating fungating tumor with little evidence of obstruction (medullary) (2) a smaller tumor which is characterized by overproduction of fibrous tissue resulting in cicatricial contraction and early stenosis (scirrhous) and (3) a large tumor in which there is over production of mucinous material with little evidence of cellular activity (colloid)

Symptomatology —The symptoms vary considerably according to the location of the lesion There is a fundamental difference in the symptomatology of neoplasia of the right and left sides of the bowel On the right side the symptoms are those of disturbed function and there is little or no evidence of obstruction due largely to the fact that the tumor is more likely to be fungating and soft and at the same time the contents of the bowel are fluid whereas on the left side the tumor is of a cicatrizing type *i.e*

scirrhous carcinoma This together with the fact that the contents of the bowel on the left side are solid results in early obstruction The patients with large fungating ulcerating tumors on the right side may suffer from a severe anemia and have alternating attacks of constipation and diarrhea They vomit frequently, are conscious of a mass in the right lower quadrant, and occasionally have fever The cause of the anemia which can be very severe is not known but it is thought that it is commensurable with the size of the growth The anemia may be so profound that it may simulate a primary anemia In fact in every unexplained severe anemia, one should consider the possibility of a malignant disease of the right half of the colon, particularly the cecum The symptoms of right sided lesions so frequently simulate those of appendicitis that in approximately 18 per cent of cases the patient is operated upon for appendicitis In lesions on the left side there is usually increased obstipation, a history of recurrent colicky pain, and also attacks of alternating constipation and diarrhea Whereas in the majority of cases the symptoms are those of progressive intestinal obstruction occasionally the first manifestations is that of acute obstruction Distention and borborygmi are frequently associated with left sided lesions Blood and mucus may be present in the stool Tumors of the transverse colon are quite readily recognized because of their superficial location and ease of palpation

Careful examination of the abdomen and digital examination of the rectum as well as proctoscopic and sigmoidoscopic examinations should be done routinely in all patients suspected of having a malignant lesion of the bowel As mentioned above approximately 75 per cent of rectal carcinomas can be palpated on digital examination Even a lesion involving the rectum and rectosigmoid can be visualized by a sigmoidoscopic examination Sigmoidoscopic examination is of value not only in visualizing the tumor but also in permitting biopsy

In addition to proctoscopic examination roentgenography is of inestimable value in the diagnosis of colonic malignancies especially in those in and above the sigmoid The barium should be introduced under fluoroscopic observation In small tumors particularly polypi the use of the double contrast visualization *i e* barium and air is of utmost importance

Prognosis—The prognosis of carcinoma of the colon is dependent upon several factors and these may be classified as (1) those which are uncontrollable and (2) those which are controllable Under the first are the age of the patient the lesion itself and associated disease The controllable factors are the duration, preoperative and postoperative management, anesthesia operative management and complications In 718 collected cases of carcinoma of the colon, the mortality rate following resection of the right sided lesions was 19 6 per cent, whereas that following the resection of the left colon was 24 4 per cent

Treatment—The treatment of malignant lesions of the large bowel is extirpation and there are few places where surgical extirpation offers such good results as in the large bowel In a series of 4561 collected cases of carcinoma of the large bowel, 58 5 per cent were operable According to Jacobson 75 per cent of the right handed lesions 80 per cent of transverse colon lesions 63 per cent of splenic flexure and descending colon lesions and only 30 per cent of sigmoid lesions were operable The fact that carcinomas of the colon remain localized for long periods of time is demonstrated by the statistics of Larson, who found that of 210 cases of carcinoma of the colon coming to autopsy 113 had either no metastases at all or only a few regional lymph nodes which were resectable Of 3911 reported resections for carcinoma of the colon 30 7 per cent had five year cures

Certainly in the presence of obstruction some type of *decompressive operation* or *defunctionalization* is desirable The Devine defunctionating colostomy in obstructive lesions of the left colon is a valuable procedure In any case some type of decompressive procedure should be done in the presence of obstruction At present the performance of one or two stage operations has caused considerable controversy Whereas most authorities have advocated two stage operations for the left sided lesions there have been many who have thought that the right sided lesions might be done in one stage In a series of right sided malignancies reported by Allen there was a de-

crease in mortality rate from 20.5 per cent with one-stage resections to 11 per cent with two stage resections Although there are many cases in which a one stage resection can be performed with impunity it might be suggested that if there is any question about the advisability of a one stage or a two stage procedure the two-stage procedure should be chosen Whereas two stage procedures have been the method of choice in carcinomas of the colon down to the sigmoid the one-stage abdominoperineal resection has been the procedure of choice in rectosigmoidal lesions

AFFECTIONS OF THE MESENTERY

Structural Abnormalities of the Mesentery—Variable structural abnormalities of the mesentery may occur and for the most part are due to failure or interruption of development at different embryological stages These consist essentially of abnormal lengthening or shortening of the mesentery lack of fusion or attachment to the posterior abdominal wall clefts and fenestrations and elongated folds and bands Various pathologic states may occur as a consequence of these anomalies Abnormal lengths of the mesentery permit the development of kinks and volvulus resulting in chronic recurrent partial obstruction or acute ileus and strangulation Various degrees of intestinal obstruction and strangulation may also be produced by the herniation of small loops into abnormal clefts fossae and elongated folds or bands The clinical manifestations depend upon the type and extent of the anomaly but in general are those of acute or chronic intestinal obstruction and usually appear in early life

Mesenteritis—The mesentery may become involved in the presence of general peritonitis just as the omental visceral and parietal casts are involved in the inflammatory process Rarely the inflammation is limited to the mesentery and the condition is known as mesenteritis The *etiology* is variable and may be due to tuberculous or pyogenic lymphadenitis or to extension of infection from the adjacent intestine the disease may follow accidental or operative trauma or it may be hematogenous from distant foci The *pathologic process* varies from a phlegmon or actual abscess formation to fibrous cicatricial thickening The latter referred to as chronic mesenteritis or mesenteritis retrahens appears as a hard, thickened shrunken fibrous mass with radiating cicatricial bands which tend to distort the regional segment of intestine and thus affect intestinal motility The *clinical manifestations* which are not characteristic are those of the primary disease or they may simulate various acute and chronic abdominal diseases *Treatment* is directed toward drainage of the abscess or release of intestinal obstruction

Mesenteric Hemorrhage—Spontaneous rupture of intra abdominal blood vessels with mesenteric or subperitoneal hemorrhage is extremely rare Arteriosclerosis and aneurysm are predisposing causes and hypertension is frequently present The vessels most commonly involved are branches of the

celiac axis and superior mesenteric artery The lesion consists of a hematoma which sometimes ruptures into the peritoneal cavity The condition frequently referred to as *abdominal apoplexy* is more common in males and in advanced age The *clinical manifestations* consist of sudden dull progressively increasing pain nausea and vomiting, and if the hematoma ruptures sudden exacerbation of pain shock and collapse Abdominal tenderness and rigidity are variable in degree *Treatment* is conservative or surgical depending upon the extent and rate of hemorrhage

Mesenteric Vascular Occlusion—Mesenteric vascular occlusion is relatively uncommon but probably occurs more frequently than is generally realized It may develop in either sex or at any age but the incidence is much higher in males and in advanced age groups The *etiologic factors* consist essentially of embolism and thrombosis inflammatory or degenerative processes obliterating the lumen external pressure or constriction and trauma Of these thrombosis of either arteries or veins and embolism of the arteries are the most common causes Vascular diseases such as endocarditis degenerative heart disease aortic atheromata aneurysms thrombo angiitis obliterans periarteritis nodosa arteriosclerosis especially of the mesenteric vessels are frequent predisposing causes Mesenteric venous occlusion is almost invariably due to thrombosis and peripheral sepsis and portal obstruction are the most common predisposing causes Septic processes which may contribute to mesenteric venous thrombosis include acute appendicitis puerperal infections phlebitis pelvic inflammatory disease diverticulitis and other inflammatory and suppurative processes in the peritoneal cavity Portal obstruction may result from various conditions including particularly cirrhosis of the liver hepatitis and hepatic abscess pylephlebitis and malignant diseases Rarely certain blood diseases such as polycythemia and leukemia may be the responsible factors Occasionally the condition appears as a postoperative complication especially following appendectomy hemorrhoidectomy or certain intestinal and pelvic surgical procedures Prolonged imbibition of alcohol has also been associated with mesenteric venous thrombosis Mesenteric arterial and venous thrombosis also may be produced by external pressure or constriction from abdominal tumors strangulated hernia intussusception or volvulus

Occlusion is more frequently arterial than venous and involves the superior mesenteric vessels much more commonly than the inferior The pathologic changes depend upon the extent and character of the occlusion Slow incomplete occlusions limited to a few small branches may produce little or no pathological change in the bowel wall because of the collateral blood supply On the other hand, sudden complete obstruction of the main vessels is more liable to produce extensive changes In either case the development of secondary thrombosis in the venous or arterial arcades is apparently the deciding factor and in the majority of cases leads to hemorrhagic infarction The affected bowel becomes swollen soggy and infiltrated with blood and assumes a cyanosed mottled dark red or plum colored appearance The lumen which is somewhat dilated contains altered blood The affected mesentery shows similar changes and appears thickened cyanosed and rigid The peritoneal fluid is usually increased and blood tinged Necrosis and perforation of the bowel are unusual but peritonitis resulting from transperitoneal migration of bacteria through the devitalized bowel wall is common

Symptoms—Clinically the condition is characterized by an acute onset of violent abdominal pain vomiting disturbed bowel function ileus and shock like manifestations Pain is the most constant and predominant symptom occasionally develops gradually but usually is sudden agonizing and persistent although frequently associated with severe colicky attacks Vomiting occurs early and is pronounced for the first few hours Constipation is common although diarrhea associated with tenesmus or alternating constipation and diarrhea may be present Melena is a fairly common occurrence In the acute fulminating cases shock like manifestations suggestive of internal hemorrhage are observed and the patient appears pale anxious and restless with a low blood pressure and a fast thready pulse Later the features of neglected intestinal obstruction appear The physical findings usu

ally do not conform with the severity of the symptoms Early the temperature may be normal or subnormal and later when peritonitis develops becomes elevated There is some abdominal tenderness and rigidity but distention occurs late A tumor is occasionally palpable and free fluid in the abdomen may be demonstrable The leukocytic count is always high *Diagnosis* is difficult for early in its course the condition is easily confused with acute intestinal obstruction and may resemble numerous other acute abdominal catastrophes such as intussusception volvulus acute pancreatitis and perforation of an abdominal viscus However the condition should be suspected in a patient with the predisposing factors who suddenly develops acute violent abdominal pain associated with vomiting shock low temperature high leukocytosis and melena Aspiration of peritoneal fluid has been suggested as a diagnostic procedure as the presence of a blood tinged fluid is almost pathognomonic

Treatment is surgical and consists essentially in resection of the infarcted segment of bowel and its mesentery with immediate or subsequent anastomosis depending upon the condition of the patient Blood and plasma transfusions are of inestimable value as preoperative and postoperative therapy The *prognosis* which depends upon the extent and period of involvement is usually bad the mortality ranging from 60 to 90 per cent

Mesenteric Lymphadenitis —Mesenteric lymphadenitis or lymphadenopathy has been classified into two types The specific and nonspecific The former occurs in association with certain specific infectious agents such as typhoid tuberculosis or syphilis and neoplastic diseases such as carcinoma lymphosarcoma or Hodgkin s disease In contradistinction to these forms in which the causal agent of the lymphadenopathy is known there is the type which has become recognized as a clinical entity and referred to as nonspecific mesenteric lymphadenitis because the etiology has not been definitely established

Nonspecific mesenteric lymphadenitis occurs more commonly than is generally realized The sex incidence is greater in females and the age incidence is highest between five and fifteen years The ETIOLOGY is controversial and among the factors suggested are allergy intestinal parasites enteritis absorption of bacterial toxins and stagnant material upper respiratory infection appendicitis filtrable viruses and specific bacterial infection The two principal routes which permit involvement of the mesenteric lymph nodes are gastro intestinal and hematogenous Whereas many believe that the appendix is the portal of entry others consider the terminal ileum as the most important site of local absorption and the oropharynx as the origin of the swallowed causative agent In the Tulane Surgical Laboratory Plank investigated sixty five cases of mesenteric lymphadenitis both histologically and bacteriologically Enterococci were obtained in pure culture in 67 per cent and a gram positive diplococcus in association with colon bacilli in 27 per cent However because the agglutination reactions and vaccine tests were negative the assumption that these organisms were the definite causative agents was considered unjustified

The CLINICAL MANIFESTATIONS of nonspecific mesenteric lymphadenitis are fairly characteristic and closely resemble acute appendicitis Pain is the most constant symptom and is usually of a dull aching character localized to the right abdominal quadrant but may be colicky and referred to the region of the umbilicus or right hypochondrium The onset is frequently acute and usually of moderate severity but recurrent attacks are common Nausea and vomiting *are fairly constant manifestations but diarrhea* and constipation are infrequently observed Of the physical signs abdominal tenderness is the most characteristic and is usually located in the right lower quadrant Frequently the tenderness extends from McBurney s or Lanz s point upward and to the left along the course of the root of the mesentery It is usually of moderate severity as is also muscular rigidity Fever is characteristically of a low grade type with temperature ranging between 99° F and 100 F There is slight or moderate leukocytosis and the differential count is usually within normal limits

TREATMENT as reported by most observers has consisted of appendectomy and the follow up results have indicated that the symptoms are relieved in a high percentage of

cases In some attacks have recurred but are usually milder and tend to abate General postoperative hygienic measures such as fresh air, sunshine, adequate diet and vitamins should also be instituted

Mesenteric Solid Tumors—Mesenteric tumors may be classified into *cystic* and *solid* forms The former are about twice as frequent as the latter The primary mesenteric solid tumors arise from the connective tissue nerves and vessels between the mesenteric leaves and retroperitoneal space In the latter instance the tumor assumes its mesenteric position by pushing its way forward between the mesenteric leaves These tumors may be benign or malignant Of the benign types the most common are lipoma fibrolipoma fibroma and fibromyoma The malignant tumors include fibrosarcoma liposarcoma, neurosarcoma myosarcoma and lymphosarcoma Lipomata are the most common of all solid tumors of the mesentery The *clinical manifestations* are variable and depend upon the type, size and location of the tumors In the benign forms there is frequently only a progressive painless abdominal swelling In some there is abdominal discomfort nausea vomiting and constipation Tumors located near the bowel may produce intestinal obstruction The malignant forms are frequently associated with progressive loss of weight and anemia The mobility of these tumors is characteristic *Treatment* is surgical and consists of enucleation or removal with resection of the adjacent intestine

Mesenteric Cysts—Mesenteric cysts occur about once in every hundred thousand hospital admissions They are found at all ages but are most common in the fourth decade and the ratio of females to males is about two to one Various theories and classifications have been presented to explain their pathogenesis In general it may be stated that they are of congenital or infectious origin The *infectious types* are less common and may be due to echinococci or tubercle bacilli The *congenital forms* may be simple embryonic cysts arising from serous or chylous structures or sequestration of embryonic diverticula during the development of the intestinal tract such as Meckel s diverticulum or they may be neoplastic arising from misplaced ovarian tissue (dermoids and teratomas) or from other urogenital tissue such as the wolffian duct and body and the mullerian body in the retroperitoneal area or from the entoderm (enterocystoma) They vary in size considerably and may be unrecognizably small or huge tumors which fill the abdominal cavity Their location also varies but they are found most frequently near the lower jejunum and ileum Pathologically the cysts are usually unilocular, although occasionally multilocular and have a fibrous wall which may contain bundles of smooth muscle, giant cells and lymph follicles Occasionally the cysts connect with the intestinal lumen by a duct The contents of the cysts vary from a clear mucinous material to a yellowish milky brown or sanguineous fluid Rarely the cysts undergo malignant degeneration

The *clinical manifestations* are variable and there are no pathognomonic features The *symptomatology* depends upon the complications produced by the cysts the most frequent of these being intestinal obstruction This may be of acute onset but usually there is a history of repeated attacks of nausea, vomiting and colicky pain associated with chronic constipation and loss of weight and strength Other complications consist of rupture with consequent peritonitis and hemorrhage into and torsion of the cyst.

Diagnosis is rarely made preoperatively but the condition should be suspected in the presence of a freely movable and cystic abdominal tumor associated with colicky pain and other manifestations of intestinal obstruction Occasionally roentgenographic studies are of value in delineating the cyst

Treatment is essentially surgical with enucleation as the procedure of choice In some cases because this is not feasible or because of strangulation or malignant degeneration intestinal resection with removal of the cyst bearing area of the mesentery is necessary

DISEASES OF THE LIVER

INTRODUCTION

The liver is probably the most important single glandular structure in the body Without it neither man nor any of the higher animals can survive more than a few hours Its known functions are numerous and doubtless others will be discovered Among the more important of these functions may be listed glycogen storage regulation (in conjunction with the pancreas suprarenals and central nervous system) of the blood sugar levels regeneration of the serum protein and the regulation of the albumin globulin ratio the manufacture and secretion of bile which in turn aids in fat digestion the production and storage of prothrombin and of the antianemic factor which regulates the maturation of red blood cells in the bone marrow the production of urea from amino acids and other detoxifying powers as for example in the acetylation of the sulfonamides and the synthesis of hippuric acid brought about by the conjugation of benzoic acid and glycine

It would be reasonable to expect that an organ charged with so many duties should be vulnerable to attack from many quarters and by various agents That this assumption is correct is borne out by the number of clinical conditions in which the liver would seem to be the principal organ affected It would be reasonable also to expect that the functions of this organ might be deranged by such attacks in varying degree and possibly in a selective manner That this is indeed the case is indicated by the results obtained in experimental and clinical studies employing the various tests designed to measure such functions One test (or several) may show impaired function while others yield normal values Presumably this is because the disease has not impaired all the functions of the liver equally The main difficulty in interpreting liver function tests would seem to lie in the fact that the liver possesses an enormous factor of safety and therefore a large proportion of the hepatic tissue must first be put out of action by disease before abnormal results can be expected in these tests Nevertheless, some progress is being made along these lines, and in the subsequent discussions of the various diseases of the liver an attempt will be made to indicate where function tests may be expected to aid in diagnosis or in estimating the degree of damage suffered by the organ The student is cautioned however against a too ready acceptance of the results of laboratory procedures and is urged to apply himself to the clinical examination and the evaluation of symptoms and physical signs the mastery of which is still most important in the study of hepatic disease

Herbert K Detweiler.

JAUNDICE

(*Icterus*)

Jaundice is a condition characterized by a yellowish staining of the skin mucous membranes and body fluids with bile pigment It is not a disease but must be regarded as a symptom with varying etiology and significance Jaundice is of three types (1) obstructive hepatic jaundice (2) hemolytic (or nonobstructive) jaundice (3) toxic or infective hepatic jaundice

The old idea that the bile pigment is manufactured or transformed in the hepatic cells has been generally discarded It is now believed that the bile pigment is formed

by the cells of the reticulo endothelial system from particles of hemoglobin liberated by disintegration of red blood cells

In the writer s opinion, the most plausible explanation of the causation of jaundice is that proposed by McNee He points out that under normal conditions the small quantity of bile pigment formed from the normal disintegration of red blood cells is carried by the hepatic artery and portal vein in the liver lobule passes through the polygonal cells of the liver into the bile capillaries and is excreted into the intestine Part of this is reabsorbed as urobilinogen and the remainder is excreted with the feces

According to this conception jaundice will occur under the following circumstances (a) when the bilirubin (bile pigment) passes through the polygonal cells in the normal manner but on reaching the bile ducts meets with obstruction (stone neoplasm etc) and has to be reabsorbed into the blood stream (b) when through toxic or infectious processes the polygonal cells are damaged and no longer able to deal with the bilirubin brought to them the bile simply passes on into the systemic venous circulation by way of the hepatic vein (c) when the rate of blood destruction results in the presence of excessive amounts of bilirubin in the blood the normal polygonal cells are unable to cope with it and allow a quantity to pass on into the general circulation (hemolytic jaundice) It is to be expected that certain clinical conditions will involve both (a) and (b)

By utilizing Ehrlich s diazo reaction van den Bergh developed a test for bilirubin in the blood This test indicates two forms of bilirubin A *direct* or *immediate* reaction is believed to indicate bilirubin which has passed through the polygonal cells and therefore is obtained in pure obstructive jaundice An *indirect* or *delayed* reaction indicates bilirubin which has not been passed through the liver cells and hence is found in hemolytic jaundice There is evidence to suggest that this type of bilirubin is bound to the plasma proteins and therefore does not pass through the kidneys into the urine In toxic or infective jaundice both forms of bilirubin are present hence a *biphasic* van den Bergh reaction The test is thus an excellent theoretical method of differentiation provided it is interpreted with the reservation that pure types of jaundice practically never occur

A van den Bergh test showing up to 0 6 units of bilirubin in the blood is considered normal Amounts up to 4 units may be present without visible jaundice (*latent jaundice*)

Obstructive Jaundice —*Etiology*—Obstructive jaundice comprising about 85 per cent of all cases may be caused by any of the following conditions

(*a*) Obstruction of the ducts from within by gallstones, inspissated bile and mucus or parasites

(*b*) Obstruction due to changes in the *walls of the ducts caused by inflammatory* swelling (cholangitis) new growths of the ducts stricture and possible spasm (Spasm has been suggested as a probable cause of so called ' emotional jaundice ')

(*c*) Obstruction of the ducts from without by pressure from new growth cysts gummata enlarged glands and adhesions and rarely by

(*d*) Kinking or torsion of the ducts which is said to be the result of displacement of the liver, stomach or right kidney

Symptoms and Signs —The symptoms and signs may be conveniently grouped according to the system involved

(*a*) Skin and Mucous Membranes —The conjunctivae first show the *yellow pigmentation* which soon appears in the skin of the entire body Care must be taken not to mistake for *jaundice the* yellowish discoloration caused by patchy masses of fat in the conjunctivae Artificial light cannot be depended upon to reveal the presence of a slight icteric tinge The color may vary from a pale yellow to a deep olive green In black jaundice the color is a greenish black and is said to be due to oxidation of the bilirubin to biliverdin

Pruritus or itching is usually present especially in chronic cases *but may* be entirely absent even when jaundice is marked Preicteric pruritus probably is not as Riesman thought suggestive of carcinoma

Eruptions on the skin are sometimes observed They may be of petechial purpuric or nodular (xanthomata) character The latter are rare and most often affect the eyelids hands and feet

(*b*) Body Fluids and Excretions —The urine varies in color from light yellow to brownish green It sometimes becomes icteric before discoloration of the skin is visible Gmelin s nitric acid test distinguishes bile pigments from blood pigment santonin etc Traces of albumin and bile stained casts are often present when jaundice is persistent or severe If obstruction of the bile ducts is complete little or no urobilin appears in the urine but if it is only partial this substance is present in normal or even increased quantities Bile salts are found with the bile pigments but because of their greater diffusibility may disappear from the urine (dissociated jaundice)

Blood —Before the bile pigment reaches the urine it must of course appear in the blood plasma The early discoloration which this produces may be of diagnostic importance when the color of the skin and sclerae is doubtful French observers have called attention to instances in which the bile salts associated with bile pigment in the blood pass into the intestine and leave the pigment behind (dissociated jaundice) Brule states that under such conditions the usual minute particles of fat (hemokonia) appear in the plasma after meals whereas when obstruction is complete this does not occur

In long standing and severe jaundice the clotting time of the blood is markedly prolonged and operations are often complicated by obstinate hemorrhage This is due to a deficiency of prothrombin in the blood and may best be obviated by the use of vitamin K together with bile salts and by transfusion of blood

Jaundice alone does not increase the leukocyte count but if prolonged may reduce the red cell count The phosphatase content of the serum is increased in obstructive jaundice normal in hemolytic jaundice and too variable in catarrhal jaundice to be of diagnostic value

Cerebrospinal Fluid Tears Sweat and Others —Tears saliva and milk are seldom stained but the sweat is often markedly tinted All tissues of the body except the central nervous system are discolored The cerebrospinal fluid is usually unaffected

(*c*) Cardiovascular System —In early uncomplicated jaundice the heart rate is slow and may be irregular The bradycardia which is due to the action of bile salts upon the cardio inhibitory mechanism may be counteracted by full doses of atropine

(*d*) Gastro intestinal System —The most striking feature of the gastro intestinal system is the change in the color of the stools Their clay colored appearance is produced by three factors the absence of bile the presence of undigested fat in quantities which according to Muller may be increased from the normal 10 per cent to 55 per cent or more and the presence of bubbles of gas which results from putrefaction caused by intestinal indigestion

Constipation often occurs as well as anorexia nausea and flatulence The liver is usually enlarged and the gallbladder is sometimes distended If the obstruction is due to a calculus in the common duct however the gallbladder is usually small because of previous inflammation (Courvoisier s law)

(*e*) Nervous System —There is usually mental depression headache drowsiness and languor In severe cases or in late stages the nervous symptoms may be very severe and consist of delirium stupor or coma (cholemia) Yellow vision so called xanthopsia is sometimes complained of and is due to pigmentation of the vitreous humor

The diagnosis prognosis and treatment of the various forms of obstructive jaundice are described under the headings of the conditions responsible

Hemolytic Jaundice (*Hematogenous Jaundice Nonobstructive Jaundice Chronic Splenomegalic Hemolytic Jaundice*) —Hemolytic jaundice is generally regarded as of splenic origin and is described in the section on Diseases of the Spleen

Toxic and Infective Jaundice —Jaundice of toxic or infectious origin is a symptom of some condition such as cinchophen phosphorus chloroform dinitrophenol or arsphenamine poisoning pneumonia septicemia Weil s disease syphilis or certain obscure intoxications The more important of these will be considered separately In all cases of toxic and infectious jaundice there is evidence of damage to liver parenchyma

Catarrhal Jaundice (*Acute Infectious Hepatitis Acute Infectious Jaundice Epidemic Jaundice*) —Definition —An acute

hepatic inflammation characterized by gastric upset and jaundice

Etiology.—The exact cause is unknown. More than half the cases occur in the school age group although the disease is encountered throughout adult life. Multiple cases are frequently seen in households and in schoolrooms. Epidemics of varying degree are not uncommon.

Morbid Anatomy.—The older conception of this disease was that it was primarily a duodenitis and cholangitis, the latter interfering with the excretion of bile with consequent absorption into the blood stream. It is now believed that in the majority of cases if not in all there is primarily an acute hepatitis with secondary involvement of the bile ducts. The liver is enlarged, smooth and greenish in color. A study of biopsy specimens reveals definite degenerative and necrotic changes in the liver lobules. The epithelium of the bile capillaries shows cloudy swelling, leukocytic exudation and epithelial desquamation. The bile is more viscid than normal and contains desquamated epithelial cells. Sometimes pus cells are also found.

In the more severe cases these changes approach in degree those found in subacute yellow atrophy or even the acute form. These pathologic findings, together with clinical experience in the rare instances where an apparently mild catarrhal jaundice develops into a condition indistinguishable from acute yellow atrophy of the liver, have led to the suggestion that these diseases have a common basis.

Symptoms and Signs.—The onset is usually insidious although in epidemics it may be sudden. There is general malaise with headache, anorexia, often nausea and vomiting, a feeling of epigastric fulness and distress. Fever is usually moderate, from 99° to 101° F, but may be higher and accompanied by chills. The bowels are apt to be constipated but there may be diarrhea. During this stage, which may last from one to three days, a tentative diagnosis of influenza is frequently made.

Not infrequently the symptoms decrease after twenty four to forty eight hours, only to be followed on the third or fourth day by the appearance of jaundice which steadily increases. In the severer cases the systemic symptoms return or become more marked and in rare instances there may be delirium and coma.

As a rule, the fever soon disappears and the lethargy and prostration lessen. The tongue is coated, the urine is very dark and the stools usually are clay colored. The pulse tends to be slow, the liver is enlarged and tender, and the spleen is usually palpable. No significant changes are found in the red or white blood cells. The van den Bergh test is biphasic and the quantitative form of this test, or the icteric index, is useful in following the course of the disease. Bile is present in the urine, but, if the stools are clay colored, there is no urobilinogen. There may be a trace of albumin and a few casts.

Itching of the skin may be a prominent feature and is not necessarily proportionate to the degree of jaundice. Both usually disappear gradually in the course of three or four weeks. Epidemic cases are frequently mild and recovery may occur in two weeks. While the jaundice may persist for six or eight weeks, the physician should consider the possibility of some other cause where the bilirubin content of the blood does not show a decrease in thirty days. Cases have been reported in which cirrhosis of the liver finally ensued.

Diagnosis.—In the young, there is rarely any difficulty in diagnosis. The mode of onset is of importance in differentiating this disease from obstructive jaundice or from infectious diseases such as pneumonia, Weil's disease and so on. One should keep in mind the possibility of an exacerbation in a case of hemolytic icterus.

In patients more than forty years of age the possibility of carcinoma of the head of the pancreas or of the biliary tract must always be considered. An insidious and painless onset should arouse suspicion. Gall stones in the common duct may easily be confused with any of these conditions and where serious doubt exists, laparotomy should be performed.

The possibility of a progressively severe case developing into the clinical picture of acute yellow atrophy should be borne in mind but should not be overlooked if careful watch is kept of the size of the liver.

Finally, the possibility of syphilis should not be forgotten. Where arsenicals have been

administered a toxic hepatitis may be pro duced

Treatment —During the acute phase the patient should be kept in bed The diet should consist mainly of carbohydrates but since there is evidence that proteins are required for liver regeneration, skimmed milk should be given in reasonable quanti ties Fats of course are poorly digested owing to the deficiency of bile in the intes tinal tract and should be kept at a mini mum Where nausea and vomiting are severe 5 per cent glucose in saline should be given intravenously in amounts of 2 000 cc per twenty four hours and food by mouth discontinued After the acute symptoms have subsided the diet may be en larged to include vegetables and fruits chicken and scraped beef A normal diet is gradually resumed as the jaundice dis appears

The bowels should be regulated with salines if necessary The total fluid intake should approximate 2500 cc daily The itch ing may be relieved by the application of calamine lotion but very often is difficult to control The slow intravenous injection of 5 cc of a 10 per cent solution of calcium gluconate will often give temporary relief

Cinchophen Poisoning—Owing to the widespread use of this drug in arthritic con ditions it is perhaps the most common chemical cause of toxic hepatitis Fortu nately relatively few individuals have an idiosyncrasy for cinchophen but those who are very susceptible may have serious conse quences from a single dose Others show signs only after continued use of the drug

Morbid Anatomy —Postmortem exami nation reveals a condition resembling acute yellow atrophy In a few of those who re cover there is a progressive fibrosis leading to the clinical picture of cirrhosis

Symptoms and Signs —Jaundice is a constant feature General malaise and gas tro intestinal disturbances are usual These symptoms may be transitory with early re covery On the other hand they may in crease the jaundice becoming intense the patient stuporous and dying in coma At the onset fever may or may not be present but in unfavorable cases there is a high fever before death

At first the liver may be enlarged but soon decreases in size There is oliguria, much bile in the urine and albumin is present

Moderately severe cases run a protracted course and complete recovery is not uncom mon A few subsequently develop cirrhosis of the liver

Diagnosis —This depends entirely on the history The taking of cinchophen (or of some patent rheumatism remedy contain ing cinchophen) is essential to the diagno sis

Treatment —There is no specific remedy The treatment is the same as for acute yel low atrophy (*q v*)

Phosphorus Poisoning—Pathogenesis — Wells has shown that the hepatic cells are killed by phosphorus and that liberation of their autolytic ferments leads to extensive breaking down of the liver As a result leu cine tyrosine cystine and sarcolactic acid are present in the blood and urine

Morbid Anatomy —All the organs under go fatty change but the liver seems es pecially damaged It becomes large friable and yellow Occasional small hemorrhages are seen Microscopically the hepatic cells show marked fatty infiltration and degen eration of the cytoplasm

Symptoms —Evidences of severe gastro intestinal irritation usually appear soon after the poison is taken Intense nausea vomit ing burning epigastric pain and profound collapse are the usual symptoms Should the patient live two or three days evidences of hepatic damage appear such as enlargement and tenderness of the liver and spleen jaundice and vomiting of grumous material (hemorrhage from mucous surfaces) Later drowsiness delirium and coma supervene and death ensues in a day or two In some patients the course is more subacute and recovery takes place

Diagnosis —A history of the ingestion of phosphorus with suicidal intent or by acci dent is important Match heads or rat paste are sometimes used The occurrence of severe gastric disturbances before the onset of jaundice is suggestive Phosphorus poison ing differs from *acute yellow atrophy* in that the liver is enlarged and the odor of the vomitus is characteristic

PROGNOSIS —The mortality is high when the hepatic involvement is marked, but many cases run a chronic or subacute course and end in recovery

TREATMENT —In the early stages gastric lavage with an oxidizing agent (peroxide of hydrogen 1–3 per cent) or old turpentine (3 cc in emulsion) is an important form of treatment The diet also is important The protein intake especially as regards meats should be strictly limited and the carbohydrate should be increased proportionately During the acute stage this can be given in the form of glucose either by mouth or intravenously Insulin, 10 units hypodermically three times a day, combined with a carbohydrate diet or with intravenous glucose has been recommended by various authors

Arsphenamine Poisoning —Whether or not the jaundice which has been observed to follow the intensive administration of arsenicals in the treatment of syphilis is sometimes a manifestation of syphilis and not the result of treatment it is certain that a severe type of toxic jaundice resembling a subacute form of acute yellow atrophy has been caused directly by such medication In this the liver is reduced in size The *symptoms* vary from a mild grade to those of acute yellow atrophy with death Strathy has called attention to the acuteness of the cardiohepatic angle as demonstrated by x ray Bailey and McKay suggest that mercury may be an etiologic factor in some instances and that the disturbance may be of the nature of a 'Herxheimer reaction in the liver The *treatment* of the condition is partly dietetic and partly medicinal The diet should be very light and relatively rich in carbohydrates Sodium thiosulfate (0 75–1 5 Gm in 15 cc freshly distilled water) is given intravenously once a day for ten days to render the arsenic in the liver and other tissues insoluble and thus retard its excretion and toxic action

Icterus Neonatorum —Jaundice of the newborn may conveniently be divided into two types (*a*) the mild form from which recovery is usual and (*b*) the severe form which usually proves fatal

The *mild type* occurs in about one third of all infants and while most commonly seen in hospitals is not infrequently encountered in private practice It is believed that this form of jaundice is hemolytic in nature being the result of a physiologic readjustment of the circulation after birth The jaundice appears about the second or third day and lasts a week or more The stools contain bile pigment but the urine does not The condition is symptomless the prognosis good, and treatment unnecessary

A rare form of mild catarrhal or infectious jaundice is caused by acute duodenitis This does not differ materially from the catarrhal disease of older children

The *severe jaundice* of the newborn is of three types (1) that due to definite *obstruction* such as congenital absence of the bile ducts syphilis of the liver or of the bile duct, and gallstones These conditions are dealt with elsewhere

(2) That caused by *thrombophlebitis* or *suppurative phlebitis* in which the infection begins at the umbilicus and extends along the umbilical vein This sometimes develops into general septicemia The pathology of the disease is that of septicemia or pyemia namely cloudy swelling of the tissues abscesses and bronchopneumonia

The jaundice appears about the fifth day with remittent fever rapid pulse and respiration vomiting diarrhea and umbilical or gastro intestinal hemorrhage the infant at first restless becomes comatose and dies

Treatment consists in the administration of enemata and minute doses of calomel as an intestinal antiseptic Antistreptococcic serum has been recommended as the *Streptococcus haemolyticus* is usually the infecting organism Sulfanilamide has now become the drug of choice

(3) *Familial jaundice of the newborn* This type of jaundice exists at the time of birth or appears soon afterward and usually affects successive infants The child soon becomes drowsy and may die in convulsions At *autopsy* the organs appear bile stained all tissues except the cortex of the brain being affected Petechial hemorrhages occur in the viscera the spleen and liver are enlarged The *prognosis* is bad Rolleston recommends administration of sodium salicylate and hexamine to the mother as a *prophylactic measure* and *treats* the infant with minute doses of calomel

The hemorrhagic tendency may be prevented by giving the mother 0 6 mg naphthoquinone (synthetic vitamin K) four times a day for two or three days prior to confinement It may also be given therapeutically to the child

Acute Yellow Atrophy —*Definition* — Acute yellow atrophy is an acute diffuse necrosis of the liver cells as the result of intoxication or infection and is characterized by a progressive diminution in the size of the organ jaundice and profound toxemia

Etiology —The condition is rare Rolleston states that he has seen it only thirteen times in thirty four years except when it was due to definite agents such as arsphenamine trinitrotoluene etc The disease is said to develop more often since the introduction of these chemicals into common use It occurs in individuals of all ages but most frequently in the third decade of life Women suffer from it more often than men probably on account of pregnancy the toxemia of which appears to be definitely related to that of acute yellow atrophy Certain infections such as syphilis are sometimes held responsible In cases associated with lues it is often difficult to determine whether the syphilitic infection or the arsphenamine treatment has brought on the condition There are cases reported however in which the jaundice of the early stage of syphilis developed into acute yellow atrophy without administration of arsphenamine Alcoholism has been followed in a few instances by acute yellow atrophy Probably any condition which leads to impairment of the resistance of the liver cells may be of etiologic significance Preexisting disease of the liver is sometimes a factor

Pathogenesis —The resemblance of the condition of the liver in acute yellow atrophy to that in various forms of poisoning (phosphorus and chloroform) indicates that the probable cause of the changes is to be found in some form of toxemia which damages the liver cells and results in subsequent autolysis and destruction It is thought that the jaundice is due to obstruction of the smaller bile ducts by viscid secretion and desquamated cells MacCallum suggests that it follows degeneration and consequent obliteration of the bile capillaries

Morbid Anatomy —The liver is greatly diminished in size the weight often being reduced to one half or one third of normal The surface appears shrunken and wrinkled The atrophy may be more advanced in the left lobe The color is yellowish green and in some areas dark red On section the liver is yellowish and contains scattered depressed areas of reddish color These are the more seriously degenerated portions When atrophy is subacute raised areas of yellowish or greenish color may be seen which are due to compensatory regeneration The marking of the lobules is indistinct especially in the red areas The liver tissue is soft and friable The bile ducts contain mucus only and the gallbladder may be empty or contain a small amount of bile

Microscopically there is such widespread degeneration of the liver cells that it is difficult to recognize the organ The lesions are more advanced in the reddish than in the yellow areas The cells are in all stages of necrosis They first become granular and bile stained then fragmentary degeneration takes place in the nuclei which soon lose their staining power In certain regions particularly around the central veins where the cells appear to undergo complete destruction only the debris and the fibrous and vascular framework of the organ can be seen The increase in fibrous tissue in such cases is only apparent Hemorrhages occur here and there between the cells

In the subacute cases the surviving liver cells at the periphery of the affected areas and the cells of the interlobular bile capillaries show evidence of compensatory regeneration (hyperplasia) This and the regeneration of the liver cells results in the formation of areas or nodules which stand out from the surrounding shrunken tissue If the disease does not rapidly prove fatal fibrotic changes may take place in the interstitial tissue (cirrhosis) Chemical investigation shows the presence of amino acids particularly leucine tyrosine and other substances the products of autolysis and destruction of the cells of the liver The quantity of fat is not increased the yellow color being due to bile

The other organs are stained with bile and often contain hemorrhages The spleen is enlarged in about half of the cases The epithe-

lium of the kidneys undergoes granular degeneration and the myocardium is softened

Symptoms—At the *onset* the symptoms are those of benign catarrhal jaundice and may in no way indicate the seriousness of the condition Most commonly this stage lasts for five or six days but in some instances—notably in syphilitic cases—persists for as long as three weeks

The *second stage* sets in abruptly with grave symptoms Severe headache restlessness, delirium, vomiting, convulsions transient paralysis, and dilatation of the pupils, which are among the prominent features, are indicative of marked toxemia and irritation of the nervous system The jaundice becomes deeper Hemorrhages may occur into the skin or from the mucous surfaces Abortion may occur The temperature usually remains low but may rise suddenly before death The disease proves fatal a few days after the onset of the severe symptoms usually after the development of coma and stertorous breathing

The liver begins to diminish in size at the onset of the second stage It becomes flabby falls away from the anterior abdominal wall and is replaced by coils of the intestine Consequently, it is extremely difficult to ascertain the exact size of the liver by percussion, because the hepatic area is tympanitic Strathy and Gilchrist point out that the cardiohepatic angle, as seen by x ray examination becomes more acute as the atrophy progresses The spleen is usually enlarged

The urine which is scanty, becomes markedly bile stained and contains albumin and casts The quantity of urea is diminished and the ammonia nitrogen content increased probably by failure of the liver to convert ammonium compounds into urea or as the result of acidosis and the fixation of ammonia by organic acids Leucine and tyrosine crystals are usually present The coagulation time of the blood is prolonged There may be moderate leukocytosis

Diagnosis—The important diagnostic features of this disease are the jaundice marked cerebral symptoms in the second stage and the progressive diminution in the size of the liver The latter point serves to distinguish acute yellow atrophy from such other forms of severe jaundice as *Weil's disease* and *phosphorus poisoning* In severe *trinitrotoluol poisoning* the liver also atrophies, but the history of exposure determines the diagnosis and is easily obtained

The line of demarcation between the clinical picture of acute yellow atrophy of the liver and that of cases not so violent in nature is less distinct than has been supposed The clinical and pathologic records of any large hospital contain cases which seem to occupy a borderline position between acute yellow atrophy and benign catarrhal jaundice

Prognosis—The disease usually proves fatal after about two weeks Occasionally the course is more subacute and the illness lasts several weeks Recovery is known to take place but is followed by the appearance of signs of cirrhosis of the liver The prognosis in pregnant women is invariably bad

Treatment—Rolleston suggests that as a prophylactic measure chloroform should never be given to jaundiced pregnant women, and that mercury should be used in treating the benign jaundice of early syphilis

The treatment of acute yellow atrophy is entirely symptomatic The toxemia is combated by subcutaneous or intravenous injection of large amounts of saline solution with 5 per cent glucose Insulin may be tried after the manner described in the treatment of phosphorus poisoning Intestinal antisepsis and purgation are advised Plenty of water with sugar should be given to combat the acidosis Bismuth may be used to relieve vomiting The diet should consist largely of cereals and milk

AFFECTIONS OF THE BLOOD VESSELS OF THE LIVER

Hyperemia may be either active or passive

Active Hyperemia or Congestion—Active hyperemia is physiologic during digestion Pathologically it results from (1) overeating alcoholism and other dietary indiscretions (2) sedentary habits (3) infections such as typhoid fever malaria and yellow fever (4) true nonsuppurative hepatitis and (5) constipation

MORBID ANATOMY—Since it is only in the infective type that there is opportunity for postmortem study of the liver little if any accurate knowledge of the pathology of this condition is available The liver is said to be uniformly congested and swollen The hepatic cells suffer little if any change

SYMPTOMS—The symptoms are a sense of fulness in the right hypochondrium headache malaise depression and indefinite digestive disturbances such as anorexia flatulence and constipation Objectively the liver is tender and slightly enlarged The sclerae are often muddy and the complexion sallow

TREATMENT—Prophylaxis consists in the avoidance of habits which predispose to the condition The actual *treatment* of the condition should consist of rest in bed marked reduction in the food intake and free purgation with calomel and salts Hot compresses poultices or mustard plasters over the liver give subjective relief After a few days the diet may be increased the patient allowed to get up and to undertake moderate exercise gradually The condition is not serious in itself and under treatment seldom lasts more than a few days

Chronic Passive Congestion—ETIOLOGY—Chronic passive congestion is very common and usually results from back pressure of blood from the right auricle in mitral stenosis or insufficiency or in chronic myocardial disease Rarely it is due to obstruction of the flow of blood from the venae cavae into the right auricle by enlarged lymph nodes mediastinal tumors or other intrathoracic abnormalities such as pulmonary emphysema fibroid lung chronic pleurisy and adherent pericardium

MORBID ANATOMY—The liver is usually markedly enlarged and engorged with blood In long standing cases structural changes always take place On section the cut surface is peculiarly variegated the dark red central portion of the lobule being surrounded by a grayish or yellowish zone which produces an appearance not unlike that of the cross section of a nutmeg hence the familiar term *nutmeg liver* Microscopic examination reveals distention of the central veins which are surrounded by shrunken poorly staining cells (pressure atrophy) and small hemorrhagic areas The cells in the outer zones of the lobules (the lighter area) are cloudy or fatty Whether pressure atrophy completely accounts for the condition of the cells in the central zone of the lobule is not certain Some pathologists emphasize the fact that the central cells are farthest from the food supply and

suffer first from starvation and lack of oxygen

When passive congestion of the liver persists for years the content of connective tissue increases particularly within the lobule (*cardiac cirrhosis*) *It is doubtful whether* this is a true cirrhosis for it seems more probable that when the liver cells atrophy the normal stroma of the liver remains and appears to comprise a greater proportion of the tissue

SYMPTOMS—The symptoms are mainly those of the associated cardiac or other underlying causes Those directly referable to the liver are pain and tenderness and a feeling of fulness over the right hypochondrium Vague digestive disorders are common and there may be slight jaundice Portal obstruction with ascites may occur before general cardiac dropsy develops The liver is enlarged tender and firm In a small proportion of cases especially in those with tricuspid insufficiency pulsation is felt

DIAGNOSIS is rarely difficult but, if the causal lesion be overlooked the large tender liver may be suspected of harboring an *abscess* If the patient be studied with particular reference to the condition of the circulation this affection as well as those of *cirrhosis hepatitis new growth* and *fatty and amyloid liver may easily be ruled out*

PROGNOSIS—The prognosis is that of the causal condition

TREATMENT—In determining the type of treatment the underlying cause is paramount Direct hepatic therapy is seldom necessary Calomel and other cathartics may be given to deplete the portal circulation

Portal Thrombosis (*Pylethrombosis Pylephlebitis Adhesiva*) —*Etiology*—Portal thrombosis occurs most commonly in cirrhosis of the liver and when malignant growths penetrate the portal vein It is also encountered occasionally in syphilis of the liver and in association with infective processes in the vicinity such as cholangitis appendicitis, and peptic ulcer Sohval calls attention to its occurrence in polycythemia vera It is said to be due in rare instances to primary portal endophlebitis

Diagnosis—The diagnosis is exceedingly difficult and in most cases is not made In a patient with hepatic cirrhosis or intra abdominal malignancy the sudden onset of ascites with other evidence of engorgement of the portal branches (hematemesis melena splenomegaly) should suggest portal thrombosis If thrombosis takes place gradually, diagnosis is impossible

Treatment is unsatisfactory, particularly in the acute cases It should be designed to relieve symptoms In *syphilitic* cases appropriate therapy is said to be of use in the earlier types The acute form usually proves rapidly fatal Recovery depends upon the establishment of an efficient collateral circulation with ultimate fibrosis of the portal vein (*pylephlebitis adhesiva*)

THE CIRRHOSES OF THE LIVER

For practical purposes it is convenient to divide the cirrhoses of the liver into two main classes portal and biliary The term cirrhosis which was first applied by Laennec refers to the tawny color of the surface of the liver in the commoner (portal) type but it has since by common usage become synonymous with fibrosis

Portal cirrhosis includes besides ordinary portal cirrhosis (the atrophic cirrhoses of Laennec) certain less common forms namely (1) the form associated with splenomegaly in Banti's disease (2) portal cirrhosis with progressive lenticular degeneration (Wilson's disease) and (3) the cirrhosis of hemochromatosis These are described elsewhere Of the biliary type there are two varieties Hanot's hypertrophic biliary cirrhosis and the obstructive biliary cirrhosis of Charcot

Portal Cirrhosis (*Laënnec s Cirrhosis Atrophic Cirrhosis Alcoholic Cirrhosis Chronic Hepatitis Hobnail Liver Gin drinker s Liver*) —*Definition* —Portal cirrhosis is a chronic disease characterized by degeneration of liver parenchyma and by periportal fibrous tissue proliferation with resulting distortion of the normal lobular pattern

Antecedent Factors —Portal cirrhosis is a disease of late middle life occurring generally between the ages of thirty five and sixty five with a peak incidence at about fifty five years Men are affected more often than women (2 to 1) Occasionally it is seen in children The incidence of this disease is high in certain countries of the Orient and Near East namely India Northern China East Indies and Syria In these regions cirrhosis has been attributed to associated diseases such as malaria dysentery and intestinal parasites In the Western Hemisphere portal cirrhosis is associated commonly with alcoholism which occurs in 50 to 85 per cent of cases in various reported series Consequently this disease is seen in occupational groups which enjoy ready access to alcoholic liquors The incidence of syphilis is relatively high (15 to 25 per cent) Many such patients however receive treatment with arsenicals which are known to injure the liver There is little evidence that hereditary or constitutional factors play a significant role

Etiology —Cirrhosis of the liver probably represents a reaction to injury that can be caused by a variety of agents some of them known and others unknown Therefore it is doubtful that a single etiologic factor accounts for all instances of the disease Parasitic infestations (*e g* schistosomiasis) may produce portal cirrhosis Certain instances of unresolved acute hepatitis or "catarrhal jaundice" may develop portal cirrhosis A relatively small number of cases result from poisons such as carbon tetrachloride cinchophen phosphorus and arsenic Although syphilis malaria and thyrotoxicosis have been classed as etiologic agents it seems more likely that they play a contributory or secondary role

Fig 77—Liver showing portal cirrhosis (Courtesy of Professor William Boyd)

In recent years interest has been directed at the alcoholic or Laennec type of cirrhosis which comprises the large majority of cases Clinical and experimental studies strongly suggest that a direct relationship exists between nutritional deficiency and the development of portal cirrhosis Whether alcoholism in this disease simply predisposes to the dietary deficiency (as in alcoholic pellagra

and beriberi) or whether it lends an added toxic effect is not clearly established

Morbid Anatomy and Pathogenesis — While the liver is usually smaller than normal, because of the contraction of the fibrous tissue and atrophy of liver cells, it is often enlarged, especially when there is much fatty change This 'fatty cirrhotic liver' is usually smooth and yellowish white not unlike that of the ordinary fatty liver but its texture is firm and the tissue cuts with resistance on account of the increased quantity of connective tissue in the portal areas In the ordinary type the surface is granular with elevations or "hobnails" the size of which varies from that of a pinhead to that of a pea or bean It is greenish yellow in color and surrounded by a greenish white depression (contracted fibrous tissue) The elevated areas are islands of regenerated liver cells which are constantly present or lobules or portions of lobules of original liver tissue On section the surface appears variegated small areas of greenish yellow or yellowish-brown being surrounded by grayish white bands of fibrous tissue The yellowish areas correspond to the elevations on the capsular surface and therefore represent the normal or hyperplastic liver tissue

Microscopically the fibrotic changes are seen to involve the portal areas In certain parts the fibrosis may be unilobular and enclose only a very small area of liver tissue but more often groups of lobules are enclosed together The liver lobules themselves are distorted or atrophied, the central vein coming to occupy an eccentric position because the degenerative changes are more marked on one side of the lobule than the other The hepatic cells may show changes of a hyaline nature in the early stages, and fatty changes are very prominent *Pigmentation* of the cells with bile and hemosiderin may be noted The latter is hematogenous in origin and may be associated with similar pigmentation in the skin and pancreas This condition is most often associated with diabetes to which the name *bronzed diabetes* is given In certain areas evidence of regeneration of the parenchyma is to be seen in the shape of new cells of large size arranged in nodular masses near the periphery of the lobule where the blood supply is most abundant The portal areas also show evidences of proliferation of the cells of the bile ducts (pseudobile canaliculi) and contain numerous well formed blood vessels derived from the hepatic artery

Fig 78 — Microscopic appearance of liver in portal cirrhosis (Courtesy of Professor William Boyd.)

The most conspicuous feature however whether on macroscopic or microscopic examination is the tremendous increase in the fibrous tissue of Glisson s capsule on the

liver surface and throughout its ramifications along the portal radicles The obvious result is a marked obstruction of the portal circulation Evidence of an attempt to overcome this by establishing an efficient collateral circulation is easily demonstrated (1) the veins at the lower end of the esophagus anastomose with the coronary vein of the stomach and form large varicose trunks (2) the inferior mesenteric veins anastomose with the hemorrhoidal veins and often give rise to well marked hemorrhoids of clinical importance (3) anastomoses form between the epigastric and portal veins by way of the para umbilical vein of Sappey Consequently a large group of varices radiating outward to join the epigastric veins (caput medusae) may form about the umbilicus Anastomoses also develop through the suspensory ligament between the portal veins of the liver and the veins of the diaphragm emptying into the vena azygos (4) through the veins of Retzius which connect the portal radicles in the intestines and mesentery to the inferior vena cava (retroperitoneal veins)

Changes in other areas are largely the result of the portal obstruction Ascites is usually a marked feature the spleen is enlarged by congestion and possibly as the result of toxemia the gastric and intestinal mucosae are congested and catarrhal and the pancreas often shows chronic interstitial fibrosis

The sequence of events in portal cirrhosis is generally believed to be (*a*) degeneration of the liver cells in the periphery of the lobules caused by poisons carried in the portal vessels (*b*) regenerative hyperplasia of the remaining liver cells and bile ducts with proliferation of the interstitial tissue and contraction (*c*) portal obstruction and the attempt to establish a collateral circulation The increase in fibrous tissue may be partly due to replacement and partly to an inflammatory reaction to the causative toxin

Symptoms—It is by no means uncommon for portal cirrhosis to exist unsuspected during life and only be found after death from accident intercurrent infection or other disease The early recognition of the disease therefore may be extremely difficult and often the first signs are those due to well developed portal obstruction such as hematemesis or ascites Careful investigation however usually reveals evidence of gastric disturbances such as loss of appetite nausea flatulence and occasional vomiting These symptoms may appear periodically Often such symptoms in an alcoholic subject are considered to be the result of alcoholism itself as indeed they may be and the onset of symptoms directly referable to the cirrhosis is frequently overlooked Sooner or later however unmistakable signs usually appear

The congestion of the gastric and intestinal mucosa produces nausea loss of appetite and even vomiting especially in the morning The bowel movements are irregular, the skin sallow, and the conjunctivae muddy Vascular spiders frequently appear on the face arms and upper trunk There is often low grade persistent fever The tongue is often coated and the breath offensive As the obstruction progresses bleeding may take place from the esophageal varices or from hemorrhoids and cause hematemesis and melena the latter often due to blood which has passed from the stomach into the bowel The hematemesis may be the first symptom but usually occurs after obstruction of the portal flow has become quite marked About 25 per cent of patients vomit blood of these approximately one third die from hemorrhage Ascites develops in about 80 per cent of cases and is a prominent feature in the great *majority of those who die of the disease* It is due apparently not only to portal obstruction but also to altered serum proteins and in certain cases to chronic peritonitis Tortuous collateral veins may be seen coursing along the distended abdominal wall and lower thorax The ascitic fluid is yellowish or straw colored with a specific gravity below 1 016 It is usually clear but may be somewhat turbid because of chronic peritonitis or previous tapping The predominating cells are endothelial in type

Peripheral edema likewise occurs commonly in these patients due presumably to changes in the serum proteins In about 80 per cent of patients the liver is palpable and firm and it frequently is tender The spleen is palpably enlarged in about one half the cases Although jaundice is not so conspicu

ous a feature here as in the biliary type of cirrhosis it is present at one or another time in about two thirds of the patients Persistent jaundice indicates activity of the disease process and it should be regarded seriously Hemorrhagic phenomena such as nosebleeds bleeding gums and pupura are not uncommon They probably are related to reduction in the plasma prothrombin

Although toxic symptoms usually develop during the later stages of the disease they may appear at any time If early they are not likely to be severe—depression headache loss of memory, and general malaise being the most common Later, or at any time more marked signs of toxemia such as delirium, drowsiness coma or even convulsions may appear The nature of the toxemia is unknown but is believed by some to result from metabolic disturbances caused by loss of liver function

Laboratory Findings—There is a tendency towards macrocytic anemia which seldom is severe However if chronic blood loss occurs there may be profound hypochromic anemia The white blood cell count is either normal or decreased Leukocytosis generally indicates the presence of some complication With the onset of failure the urine becomes decreased in amount concentrated and contains an excess of urobilinogen The serum bilirubin or icterus index usually shows slight elevations from time to time and rarely shows marked increases The serum proteins may be altered early in the disease Characteristically there is decreased serum albumin and increased serum globulin Whereas the serum globulin values are variable the serum albumin values correlate fairly well with the clinical course That is the serum albumin tends to increase during clinical improvement and to decrease during failure A value below 2 5 Gm per cent is of serious import Plasma prothrombin is reduced in about one half the cases The administration of vitamin K fails to restore normal values for prothrombin in the presence of severe liver damage Indeed this failure to respond to vitamin K therapy has served as a test for impaired liver function The plasma fibrinogen however is usually normal The nonprotein nitrogen is unaltered except terminally when it may rise The serum total cholesterol cholesterol ester and alkaline phosphatase may be normal or moderately reduced

Since the liver has many functions no single test can give an overall index to its competence It is advisable therefore to employ several tests which measure different functions For example the bromsulfalein dye test and bilirubin excretion test are measures of excretory function the urine urobilinogen is a measure of pigment metabolism, the intravenous galactose test is a measure of carbohydrate function The hippuric acid test may or may not be altered in this disease Other tests which depend upon the presence of abnormal serum proteins in cirrhosis have been useful as diagnostic aids These include the cephalin flocculation reaction Takata Ara, and colloidal gold tests Whereas they may occasionally give false positive values it is seldom that these tests are negative in the presence of liver disease

Complications—It is often difficult to distinguish sharply between what may be regarded as less common symptoms and complications The supervention of *acute infection*, such as pneumonia erysipelas peritonitis phlebitis and endocarditis is frequent and serious These infections account for about 25 per cent of the deaths from cirrhosis With the advent of sulfonamide drugs, this danger has been lessened In general the sulfonamides (sulfadiazine) are well tolerated by these patients Whereas active *tuberculosis* was formerly a common complication it has been reported in only 2 or 3 per cent of the cases in recent series

Portal cirrhosis is often complicated by *abdominal hernia* This is due presumably to increased intra abdominal pressure *Peptic ulcer* occurs in possibly 5 to 10 per cent of cases In certain instances of cirrhosis hematemesis has been due to complicating peptic ulcer rather than to the suspected rupture of a varix *Portal thrombosis* occurs rarely It seems to be more frequent in patients who have experienced abdominal surgery It also may be found in those cases of cirrhosis (4 per cent) that develop *primary carcinoma* of the liver

Diagnosis—During the early stages of portal cirrhosis the symptoms are so vague that definite diagnosis is often very difficult

In an alcoholic patient or an individual who has led an irregular life persistent dyspepsia with repeated attacks of biliousness and perhaps slight jaundice should arouse suspicion of early hepatic cirrhosis Added confirmation is given if the liver be enlarged and tender and the spleen enlarged Later the hepatic facies is characteristic, the patient is thin the eyes sunken the nose sharp distended venules appear on the nose and cheeks and the skin is muddy or subicteroid Definite signs of portal obstruction render the diagnosis certain

The ordinary portal cirrhosis can be differentiated from the *syphilitic type* by the absence of a history of infection and a negative reaction to the Wassermann test It must be kept in mind however that syphilis may and often does exist in a patient with nonsyphilitic portal cirrhosis Hematemesis without ascites may suggest *peptic ulcer* In this condition pain has a definite relationship to the taking of food and the liver and spleen are not enlarged Fluoroscopic examination after a barium meal helps to exclude the possibility of ulcer and *malignant disease* of the gastro intestinal tract

Primary carcinoma of the liver may be indistinguishable in its symptoms and signs from portal cirrhosis This is to be anticipated since primary carcinoma generally is superimposed on cirrhosis of the liver If the liver increases rapidly in size or if there is hemoperitoneum the diagnosis of malignancy should be considered *Secondary carcinoma* of the liver usually shows evidence of spread elsewhere Occasionally metastases are confined to the liver In such instances diagnosis is difficult for the clinical picture may simulate cirrhosis closely *Adherent pericardium* with persistent ascites may be mistaken for portal cirrhosis The elevated venous pressure and disturbed cardiodynamics however serve to differentiate this condition clearly from portal cirrhosis

Prognosis—Accurate prognosis is impossible because of the wide variations in the course of the disease At times when there are no major symptoms the disease may remain unrecognized throughout life and the victim die from some other cause Again the disease may be acute and end fatally in a few months The great bulk of cases fall between these extremes and the average duration from the onset of definite evidence of cirrhosis until death is about two years

When signs of liver failure appear such as ascites jaundice and hematemesis the prognosis immediately becomes grave After the onset of ascites about half the patients survive six months and about one third survive one year In the opinion of certain authors jaundice bears a similar prognostic significance in patients with cirrhosis In the case of hematemesis about one third die shortly after the first episode and an additional third die by the end of the first year However recent changes in therapy—notably treatment with dietary measures and the control of intercurrent infections with sulfonamides—may modify considerably the grave outlook previously taken of this disease

Treatment—In the preascitic stage and before hematemesis has occurred the therapeutic measures should rectify the patient s mode of life and personal hygiene When signs of liver failure appear such as ascites or jaundice the patient should be placed at bed rest Alcohol should be prohibited Although anorexia may be present the patient should be urged to eat He should be fed a nutritious high caloric diet of high protein (110–120 Gm) moderate carbohydrate and fat content Meat fish milk eggs fruit and green vegetables should constitute the bulk of the diet A satisfactory regimen includes eggs for breakfast meat at luncheon and supper milk at each of three meals In addition a milk drink containing powdered brewers yeast (15–25 Gm) may be given twice daily between meals If powdered yeast is not tolerated vitamin B complex should be substituted in the form of liquid yeast concentrates Thiamin chloride (5 mg) and unconcentrated liver extract (5 cc) may be injected intramuscularly twice weekly The treatment should be pursued diligently over a period of months According to recent reports upon following the above dietary program a significant number of patients have experienced the loss of ascites and have made considerable clinical improvement

Fluids are allowed up to about 2 liters daily in patients with ascites Salt should be restricted to the amount ordinarily used in the kitchen in preparing the food Ab

dominal taps should be done before distention interferes seriously with the patient's appetite In order to lengthen the intervals between paracenteses, mercurial diuretics may be injected once or twice weekly together with ammonium chloride by mouth If the prothrombin is low vitamin K should be administered, and if hypochromic anemia is present ferrous sulfate may be given

For hematemesis the patient should be kept absolutely quiet in bed and all food omitted for two or three days An ice bag should be placed over the epigastrium, and if the patient is restless, morphine given hypodermically in small amounts If hemorrhage is severe transfusion of fresh citrated blood should be given early and if signs of hemorrhage persist the transfusion should be repeated Vitamin K concentrates may be given parenterally Hypodermoclyses of normal saline should be given if the patient is dehydrated Semiliquid and later soft diets may then be instituted

In the past surgical procedures such as omentopexy and splenectomy have been advocated for the treatment of portal cirrhosis The consensus of opinion at present is that the results obtained do not justify the risks involved in these operations

Biliary Cirrhosis —Two forms of biliary cirrhosis are recognized the primary (Hanot), and the secondary or obstructive (Charcot)

Primary Biliary Cirrhosis (*Hypertrophic Biliary Cirrhosis Infective Biliary Cirrhosis Hanot s Cirrhosis*) —Definition —Primary biliary cirrhosis is a chronic disease of the liver characterized clinically by persistent jaundice with enlargement of the spleen and liver and anatomically by a catarrhal inflammation of the small bile ducts and intralobular fibrosis

Etiology and Pathogenesis —It is a rare disease which occurs in youth and early adult life Males are more often affected than females Boyd points out that the condition is not an entity but includes two or three conditions the most important of which is infective He suggests that the name Hanot be dropped Although the disease is said to be familial or even hereditary in certain cases a definite distinction has not always been clearly made between Hanot s cirrhosis and hemolytic (familial) jaundice The immediate cause is unknown Primary biliary cirrhosis has in a number of instances, definitely followed an infection, such as typhoid fever This fact and the clinical picture have led most observers to regard infection as the most probable cause of Hanot s cirrhosis The usual absence of evidence of infection in the duodenum and larger bile ducts renders the possibility of an ascending infection unlikely, and Rolleston inclines to the view that the infection (or toxin) reaches the small bile ducts through the hepatic artery The fibrotic changes are believed to be secondary to the cholangitis

Morbid Anatomy —The liver is uniformly enlarged sometimes weighing 3800 Gm The surface is smooth or finely granular dark green in color, and may show some perihepatic adhesions The organ is firm in consistency, cuts with resistance, and presents a uniform granite like yellowish green appearance Microscopically a dense fibrosis can be seen to surround the individual lobules and small bile ducts It may actually extend into the lobule (intralobular fibrosis) The liver cells themselves do not undergo any marked change and the larger bile ducts are likewise comparatively unaffected

In the portal areas the smaller bile ducts show evidence of catarrh and proliferation and in many cases contain dark staining columns of cells, the so-called *pseudobile canaliculi* These structures are formed in an attempt at regeneration, a reactive hyperplasia of the cells of the bile ducts

When the disease is advanced the picture may be confused by the development of multilobular cirrhosis Indeed it is often very difficult to classify certain borderline cases from a histologic standpoint

The spleen is enlarged and shows endothelial proliferation and fibrosis The periportal lymph nodes are enlarged and often all the glands All the organs are stained with bile

Symptoms —The *onset* which is insidious is sometimes manifested by vague gastro intestinal symptoms such as mild dyspepsia pain vomiting and diarrhea Often the first definite symptom is jaundice, but this may be preceded by pruritus The jaundice is usually slight but persistent it may vary in degree from time to time The

urine and feces contain bile The liver is found to be enlarged and may be tender The *spleen* is palpable Periodic attacks of mild fever abdominal pain leukocytosis and progressive hepatic and splenic enlarge ment and tenderness may occur There is no evidence of portal obstruction unless multi lobular fibrosis supervenes in the advanced stage

The *course of the disease* is chronic the symptoms gradually becoming more pro nounced and the general nutrition of the pa tient failing as time elapses Three to six years is a common duration Death results from an acute degeneration of the liver cells resembling acute yellow atrophy or from profound cachexia In the later stages hem orrhages into the skin and from the mucous membranes may occur Clubbed fingers have been noted

Diagnosis —The insidious onset in young persons of a mild but persistent jaundice gastro intestinal disturbance enlargement of liver and spleen and periods of slight fever leukocytosis and abdominal pain should suggest hypertrophic biliary cirrhosis The condition must be differentiated from *portal cirrhosis* (age signs of portal obstruc tion history of alcoholism) from *cholelith iasis or other types of obstructive jaundice* (history deep jaundice clay colored stools slight enlargement of liver and spleen) and from *hemolytic jaundice* (acholuric urine increased fragility of red cells)

Treatment —The disease cannot be defi nitely arrested The general health should be maintained in so far as possible by care ful avoidance of exposure to cold and wet a generous but simple diet and plenty of sun light and fresh air The pruritus may be relieved by measures already recommended for that of other types of jaundice Admin istration of calomel (grain 1/8 3 times a day for several days) has been recommended Drainage of the gallbladder and bile ducts gives good results in certain cases but has not come to be a routine method of treat ment Lyon s method of nonsurgical drain age of the gallbladder and bile ducts by the duodenal tube may produce equally good results without incurring danger W J Mayo has reported that splenectomy was a successful form of treatment in three cases

Obstructive Biliary Cirrhosis (*Secondary Biliary Cirrhosis Charcot s Cirrhosis*) — Obstructive biliary cirrhosis results from the proliferative fibrosis brought on by chronic obstruction of the larger bile ducts by gall stones new growths or adhesions As the name implies the fibrosis extends out from the intrahepatic bile ducts and produces a condition not unlike that of Hanot s cirrho sis except for the less marked enlargement of the liver A cholangitis involving the larger bile ducts is also present The gall bladder may or may not be distended according to the nature of the obstruction (see *Courvoisier s Law*)

Symptoms —The symptoms are those of the cause of the obstruction and those of chronic obstructive jaundice The liver is defi nitely enlarged and firm Recurring attacks of chills and fever (Charcot s intermittent hepatic fever) are common The spleen is not uniformly palpable as in Hanot s disease

Treatment —The treatment is that of the cause of the obstruction and is usually surgical

ABSCESS OF THE LIVER

(*Suppurative Hepatitis Purulent Hepatitis*)

Etiology —Suppurative hepatitis or ab scess of the liver is always due to infection The organism may be carried to the liver by

either the portal or hepatic blood stream, by the bile passages after suppurative cholangitis by direct extension from neighboring infection and from external sources by traumatism

The commonest type is that in which multiple abscesses develop as a result of infection by emboli from foci in the area drained by the portal vein or as a manifestation of a general pyemia in which the infective agent reaches the liver through the hepatic artery Rarely the infection has been known to be carried in the hepatic veins (retrograde emboli) In the portal area the emboli arise from ulcerative disease of the gastro intestinal tract from acute appendicitis rectal and pelvic infections and following rectal or low abdominal operations for herniae hemorrhoids and others In such cases as Osler points out the abscesses are as a rule within the branches of the portal vein (suppurative pylephlebitis) If infection takes place by way of the hepatic artery it is secondary to such conditions as ulcerative endocarditis septicemia and pyemia

Tropical abscess (*solitary abscess*) is usually single and is caused almost always by infection with the *Entamoeba histolytica* As its name implies the disease occurs most commonly in tropical climates It is ordinarily the result of previous amebic dysentery but may develop without infection of the bowel Overindulgence in alcohol and overeating are said to be predisposing factors The incidence is higher among the foreign population in India than among the natives The route by which the organism reaches the liver is not definitely known but the general weight of opinion is that it travels by way of the portal vein Amebic abscesses may form many years after an attack of dysentery

Suppurative cholangitis is not an uncommon precursor of hepatic abscess The infection spreads by extension along the bile ducts into the liver substance Direct extension may also occur from an infected gall bladder from subphrenic abscess or other suppurative lesion in the vicinity of the liver

Traumatism is not a frequent cause of abscess of the liver It may occur as a result of accidental injury or of a stab wound in which the bacteria are introduced directly from without The causative wound need not be perforating as injury to the liver from indirect contusion or laceration may cause the localization of blood borne organisms which come from infections elsewhere in the body

The ordinary pyogenic organisms such as *Streptococcus Staphylococcus Pneumococcus Bacillus coli* are those usually present in the abscess Occasionally *Bacillus typhosus* or *Bacillus dysenteriae* may be found The tubercle bacillus and the ray fungus (*Actinomyces*) are rarely encountered

Hydatid cysts in the liver may become infected with pyogenic bacteria and cause an abscess Rarely the presence of round worms and flukes in the liver causes a purulent hepatitis

Morbid Anatomy—The tropical or amebic abscess is usually single and, in about 75 per cent of cases situated in the right lobe The abscess may be very large and contain a surprising amount of material As much as 8 quarts of fluid have been taken from a single abscess Externally there may be perihepatic adhesions especially to the diaphragm The abscess cavity is lined at first with rough necrotic tissue but later the walls become smoother as fibrous tissue surrounds the abscess and invades the neighboring parts of the liver The contents of the abscess are usually reddish brown in color glairy in consistency and under the microscope can be seen to contain broken down liver and blood cells and *Entamoeba histolytica* Leukocytic infiltration of the wall is not the rule An amebic abscess is therefore really an area in which necrosis and digestion of the tissue have occurred rather than a true abscess In a certain number which become secondarily infected with pyogenic organisms creamy pus is present Sometimes the amebae can be found in the wall of the abscess when examination of the contents fails to reveal them

Solitary abscesses of the liver are also occasionally caused by bacterial infection particularly in cases of traumatism

Pyemic abscesses and those secondary to suppurative cholangitis are usually multiple The former type may be miliary and are distributed along the course of the blood vessels while the latter extend into the liver substance from foci in the bile ducts Fre-

quently multiple abscesses coalesce so that the whole area involved assumes a spongy appearance because of the uneven areas of necrosis and liquefaction

The contents of the nonamebic abscesses are definitely purulent and contain many pus cells as well as detritus from broken down tissue

In suppurative pylephlebitis the infection originates in the area drained by the portal vein (appendiceal abscess ischiorectal abscess) and sets up first a portal periphlebitis The inflammation extends inward involving the intima and resulting in thrombosis The thrombus becomes infected softens and in breaking down forms pus The process may be extended to the liver by direct continuity or by infected emboli from the suppurating area The liver is uniformly enlarged and its entire portal area may be involved in the suppuration The abscesses may be separate and produce a honeycombed appearance or may coalesce

Symptoms —*Solitary Abscess* —Often a solitary hepatic abscess produces no special symptoms and may be unsuspected during life (latent abscess) Usually however a fairly definite syndrome permits correct diagnosis In amebic infections the symptoms may develop during or after an acute attack of dysentery The onset may be sudden but is often insidious Malaise intermittent fever chills pain in the right upper quadrant with enlargement and tenderness of the liver leukocytosis and slight jaundice are commonly present The chills and intermittent fever often suggest malaria Profuse sweating is common The pain is variable often radiates to the right shoulder or scapular region and if the abscess approaches the surface may be sharp and stabbing in character It is aggravated by deep breathing and palpation With perihepatitis a friction sound may be heard over the liver As a rule the patient is most comfortable when lying on the right side or back turning to the left side often produces a dull aching or dragging sensation in the right hypochondrium Loss of appetite weakness emaciation and a septic appearance are usually present and progressive

When the abscess is deeply situated the enlargement of the liver may be slight at first and there may be no change in the contour of the organ Later when the abscess has attained a large size or when it is situated anteriorly and toward the lower margin the enlargement is easily demonstrable and a bulging of the right side of the abdomen may be detected If the abscess is close to the diaphragmatic surface of the right lobe an upward displacement of the right lung is evident on percussion and can be seen in x ray plates Abdominal breathing is restricted

Jaundice develops in only 15 per cent of patients and is not marked A pale muddy or sallow appearance of the skin with subicteric tinting of the sclera is however usual Nausea and vomiting may occur and intestinal irregularities (diarrhea constipation) are common

Ascites is rare and the spleen is seldom enlarged

Pyemic Abscess and Suppurative Pylephlebitis —The symptoms of pyemic abscess and suppurative pylephlebitis are masked to a large extent by those of the primary disease The clinical picture is that of general septicemia or localized septic infection such as appendiceal abscess pyonephrosis lung abscess or other infection likely to give rise to pyemia Chills sweats remittent fever with malaise vomiting weakness wasting slight icteroid tinging of the skin and conjunctivae and tenderness over the liver are suggestive There are however no signs pathognomonic of involvement of the liver and usually the multiple abscesses are but one manifestation of the original infection There is usually a pronounced leukocytosis (polymorphonuclear) in this type of hepatic abscess

Complications —The abscess may rupture if not operated on This occurs not infrequently and the rupture takes place most often through the diaphragm and pleural sac into the lung A lung abscess is thus produced which may in turn rupture into a bronchus If the infection be amebic the sputum is then brownish (anchovy colored) and contains shreds of liver tissue and amebae Rupture may also occur into the bowel into the peritoneal sac and rarely into the pericardium Secondary abscesses in the lungs are not uncommon

Diagnosis of abscess of the liver is often difficult A history of dysentery the devel

opment of a clinical picture of sepsis (chills sweats irregular fever), and signs of hepatic involvement (enlargement tenderness pain in hepatic region) constitute the most significant signs in the amebic cases X-ray examination may be valuable In pyemic abscesses the clinical picture is that of pyemia or septicemia and often there is little evidence of involvement of the liver although enlargement pain and tenderness over the liver may suggest the correct diagnosis

In malarial regions the condition must be differentiated from *malaria* Examination of the blood for the malarial parasite the leukocyte count and the therapeutic test with quinine suffice for this Liver abscess may be distinguished from *suppurative cholangitis* by the occurrence in the latter of earlier and more pronounced jaundice and a frequent history of cholelithiasis In 'intermittent hepatic fever associated with *gall stones* the differential features are the paroxysms of pain chills sweats followed by deepening jaundice with afebrile and (usually) apparently normal intervals If the hepatic abscess is large and located in the upper part of the liver the diaphragm may be high and the lung compressed Such a condition may suggest *empyema* but the history the limits of dulness on percussion and the x ray findings usually suffice for differentiation Diagnostic puncture of the liver may be employed if the presence of a solitary abscess is suspected but involves some risk of hemorrhage and peritonitis Blood examinations (cultures counts parasites Wassermann test) should prevent confusion with *syphilis of the liver trypanosomiasis typhoid fever leukemia* and *malignant endocarditis* The history complement fixation test and exploratory puncture sometimes permit diagnosis of a suppurating *echinococcus cyst* in the liver

Prognosis—Multiple abscesses of the liver are practically always fatal whether they be due to suppurative pylephlebitis pyemia or extension from suppurative cholangitis Solitary abscesses on the other hand may not prove fatal when rupture takes place into the bowel or even into the lung or when surgical evacuation is successful If the abscess remains intact death usually results from toxemia or pyemia

Treatment—The treatment of *solitary abscesses* due to pyogenic infection is surgical together with sulfonamide therapy appropriate to the type of bacterium involved. Evacuation and drainage of the abscess should be performed as soon as the diagnosis is made If the infection is amebic emetine 1 grain hypodermically for six successive days, ½ grain for four successive days, should be given as well Repeated aspiration of single abscesses has been recommended by some observers as preferable to open drainage Surgical drainage of amebic abscesses has few remaining advocates

General therapy consists of absolute rest in bed, light diet application of poultices or compresses to the hepatic region and regulation of the bowels During convalescence, open air nourishing food and tonics are advisable

The treatment of *pyemic abscesses* and *suppurative pylephlebitis* is largely symptomatic and palliative since these conditions are almost invariably fatal Cases have recently been reported however in which recovery has taken place after sulfanilamide therapy

MALIGNANT DISEASE OF THE LIVER

Under the heading of malignant disease of the liver carcinoma and sarcoma of the liver both primary and secondary will be considered

Incidence and Etiology—*Primary carcinoma* of the liver is rare but is seen more often than primary sarcoma of the liver It is more common in males than females and occurs in individuals about fifty years of age There is however a wide range as far as age is concerned The writer recently ob

served a case in a young woman of twenty one *Secondary carcinoma* of the liver is very common and develops in about 50 per cent of all the victims of malignant disease The primary growth responsible for the sec ondary metastases in the liver is most com monly found in the stomach but frequently occurs in other parts of the digestive tract especially in the colon Not infrequently the primary lesion is in the breast the eye the pancreas the gallbladder or the genito urinary tract (prostate uterus and so on) Females are slightly more susceptible than males (four to three) probably because of the frequency of cancer of the uterus The patients are usually more than forty years of age

Primary sarcoma of the liver is extremely rare *Secondary sarcoma* constitutes nearly 10 per cent of malignant disease of the liver and is most frequently due to metastases from primary growths in bones adrenals mediastinum the eye and the skin The age incidence is that of sarcoma in general and is therefore lower than that of carcinoma

Morbid Anatomy.—Eggel divides *primary carcinoma* of the liver into three types (1) the nodular and common form in which there are scattered tumors throughout the organ (2) the massive form in which a single large neoplasm is found often with small metastatic nodules in its vicinity and (3) the diffuse form in which the whole liver is infiltrated with small cancerous nodules surrounded with marked connective tissue hyperplasia This latter type gives rise to a gross picture very like that of cirrhosis of the liver which can often be recognized as malignant only on microscopic examina tion Rolleston believes that the cirrhosis is primary and that the carcinoma is the out come of hyperplasia of the hepatic cells

Secondary carcinoma appears as multiple grayish white nodules of varying size and number which when superficial often cause the surface of the liver to bulge and form definite bosses which may be umbilicated Frequently these bosses are palpable through a thin abdominal wall The liver as a whole may be enormously enlarged Christian re- ports that in one case it weighed 33½ pounds The nodules on section often show central areas of degeneration and hemor rhage so that the original firm consistency is lost The shrinkage of the necrotic center and the contraction of the fibrous tissue pro duce the umbilication mentioned above Microscopically the tumor presents the char acteristics of the primary lesion and is most commonly alveolar or columnar in structure

Primary sarcoma of the liver is usually a massive growth The tumor is often hemor rhagic and may break down in the center to form pseudocysts In another form there are multiple nodules and occasionally a third type is seen which shows diffuse infil tration resembling that in the liver in con genital syphilis Secondary sarcoma may be of the melanotic type the primary lesion being in the eye or less commonly in the skin Less important types are lymphosar coma and myxosarcoma

Symptoms.—The onset is very insidious and is manifested by weakness loss of ap- petite and failure in general health As in the case of malignant disease elsewhere there is usually progressive loss of weight and increasing secondary anemia

Symptoms indicative of involvement of the liver itself may arise at any time These are usually discomfort or pain in the right hypochondrium jaundice and ascites It is often impossible to distinguish primary malignant disease of the liver from the sec- ondary type unless there is evidence of a primary growth elsewhere

The enlargement of the liver is usually progressive Often the irregular bulging of the right hypochondrium can be seen through a thin abdominal wall and on palpation the bosses with their umbilicated centers may be felt In such cases the diagnosis is certain In other patients however the liver is not enlarged and definite diagnosis is im possible Jaundice which is apparent in about 50 per cent of cases is usually due to pressure of a cancerous nodule upon the intrahepatic bile ducts but may be caused by the pressure of enlarged glands on the larger ducts Ascites is common but is not seen as frequently as jaundice It may be due to pressure upon the portal vein by tumor nodules to an associated hepatic cirrhosis to perihepatitis or to extension of the growth to the peritoneum The spleen is usually not enlarged

Irregular fever is a common symptom which may be caused by the cancer itself

opment of a clinical picture of sepsis (chills sweats, irregular fever), and signs of hepatic involvement (enlargement, tenderness pain in hepatic region) constitute the most significant signs in the amebic cases X ray examination may be valuable In pyemic abscesses the clinical picture is that of pyemia or septicemia, and often there is little evidence of involvement of the liver although enlargement, pain and tenderness over the liver may suggest the correct diagnosis

In malarial regions the condition must be differentiated from *malaria* Examination of the blood for the malarial parasite, the leukocyte count, and the therapeutic test with quinine suffice for this Liver abscess may be distinguished from *suppurative cholangitis* by the occurrence in the latter of earlier and more pronounced jaundice and a frequent history of cholelithiasis In intermittent hepatic fever' associated with *gall stones* the differential features are the paroxysms of pain chills, sweats followed by deepening jaundice with afebrile and (usually) apparently normal intervals If the hepatic abscess is large and located in the upper part of the liver the diaphragm may be high and the lung compressed Such a condition may suggest *empyema* but the history, the limits of dulness on percussion and the x ray findings usually suffice for differentiation Diagnostic puncture of the liver may be employed if the presence of a solitary abscess is suspected but involves some risk of hemorrhage and peritonitis Blood examinations (cultures counts parasites Wassermann test) should prevent confusion with *syphilis of the liver trypanosomiasis typhoid fever leukemia* and *malignant endocarditis* The history complement fixation test and exploratory puncture sometimes permit diagnosis of a suppurating *echinococcus cyst* in the liver

Prognosis—Multiple abscesses of the liver are practically always fatal whether they be due to suppurative pylephlebitis pyemia or extension from suppurative cholangitis Solitary abscesses on the other hand may not prove fatal when rupture takes place into the bowel or even into the lung or when surgical evacuation is successful If the abscess remains intact death usually results from toxemia or pyemia

Treatment—The treatment of *solitary abscesses* due to pyogenic infection is surgical together with sulfonamide therapy appropriate to the type of bacterium involved Evacuation and drainage of the abscess should be performed as soon as the diagnosis is made If the infection is amebic emetine, 1 grain hypodermically for six successive days, ½ grain for four successive days should be given as well Repeated aspiration of single abscesses has been recommended by some observers, as preferable to open drainage Surgical drainage of amebic abscesses has few remaining advocates

General therapy consists of absolute rest in bed light diet application of poultices or compresses to the hepatic region and regulation of the bowels During convalescence open air, nourishing food and tonics are advisable

The treatment of *pyemic abscesses* and *suppurative pylephlebitis* is largely symptomatic and palliative since these conditions are almost invariably fatal Cases have recently been reported however, in which recovery has taken place after sulfanilamide therapy

MALIGNANT DISEASE OF THE LIVER

Under the heading of malignant disease of the liver carcinoma and sarcoma of the liver both primary and secondary, will be considered

Incidence and Etiology—*Primary carcinoma* of the liver is rare but is seen more often than primary sarcoma of the liver It is more common in males than females and occurs in individuals about fifty years of age There is however a wide range as far as age is concerned The writer recently ob

neath the capsule Rarely, they enlarge during adult life and produce clinical signs such as bulging of the abdomen ascites or other symptoms of pressure Solitary and multiple *adenomata* may occur The latter type which is found in some cases of portal cirrhosis is regarded by some as merely an excessive hyperplasia of the liver tissue It is difficult to draw the line between hyperplastic areas and adenomata and between adenomata and carcinomatous nodules Some pathologists consider the adenoma a transitional stage between hyperplasia and malignancy

HERBERT K DETWEILER

CYSTS OF THE LIVER

Simple cysts are usually small and single They are commonly attributed to local obstruction of the bile ducts either congenital or associated with inflammatory change They have no clinical significance

Cystic disease of the liver is a rare condition usually associated with congenital cystic kidneys The cysts are usually small multiple and filled with a clear serous fluid The condition is probably congenital although it is seldom recognized until adult life and then only if the kidneys are affected

Echinococcus cysts are discussed elsewhere

DEGENERATIVE DISEASES OF THE LIVER

Fatty Liver—It has been the custom to consider fatty lesions of the liver as of two types—infiltrative and degenerative The former type has been thought to be a condition in which fat derived from the usual fat deposits in other parts of the body is deposited in the liver after transportation by way of the blood stream without any actual damage to the liver cells whereas the latter type has been thought to be a primary degeneration of the protoplasm of the liver cells into fat This distinction is not as sharp as such classification would imply since in certain conditions such as phosphorus poisoning in which the lesion is usually regarded as degenerative some of the fat in the liver is derived from other parts of the body Clinically however the degenerative types form a rather definite group including phosphorus arsenic alcohol and chloroform poisoning acute yellow atrophy and occasionally acute infections The infiltrative type is commonly found in (*a*) obesity (*b*) conditions supposed to reduce the oxidative powers of the body such as anemia cachexia and pulmonary tuberculosis and (*c*) infections such as septicemia typhoid fever, and the acute exanthemata

Morbid Anatomy—The fatty liver is usually uniformly enlarged smooth with rounded edges and pale It is greasy on section and as a rule appears rather bloodless In cases associated with passive congestion however it may present the characteristic nutmeg appearance Microscopic examination reveals in the liver cells fat droplets usually of large size which press the protoplasm and nucleus aside The most marked change is toward the periphery of the lobule In the degenerative types the liver may be smaller than normal This reduction in size is often extreme in acute yellow atrophy The fat droplets are usually minute and the cell nucleus and the cytoplasm show evidence of degeneration In many cases of fatty liver both types of change are simultaneously present

Symptoms—The clinical picture is mainly that of the associated disease Symptoms referable to the liver itself may be absent but a sense of fulness and discomfort in the hepatic region is often noted Jaundice ascites and pain are absent in the simple cases Vague gastro intestinal disturbances may occur

Diagnosis—The association of one of the causative conditions cited above with the presence of an enlarged smooth soft and painless liver without jaundice should suggest fatty change In obese subjects it may be difficult to determine the size of the organ The history the associated conditions examination of the spleen and the blood findings help to differentiate fatty liver

or by suppuration in a degenerating cancerous nodule The blood examination reveals a secondary anemia and frequently a moderate leukocytosis The urine contains bile pigment when the jaundice is deep A positive Wassermann reaction in the blood without other evidence of syphilis has been reported In one such case in the writer's experience the reaction was persistent but antisyphilitic treatment had no effect on the progress of the disease It is probable that the latent syphilis had no relation to the neoplasm

Diagnosis —An insidious onset with progressive nodular enlargement of the liver anemia and loss of weight and strength in a person at or past middle age are characteristic signs The diagnosis is conclusive if a primary malignant growth elsewhere be demonstrable The presence of jaundice and ascites is additional evidence Aspiration biopsy is a justifiable procedure in doubtful cases

It is often impossible in the absence of signs of a primary lesion to distinguish between primary and secondary malignancy of the liver The primary focus may be latent

Syphilis of the liver may be recognized by the history of infection the evidence of luetic lesions elsewhere in the body the blood examination and the therapeutic test As pointed out above the possibility of the coexistence of these diseases must be kept in mind An *echinococcus cyst of the liver* may simulate cancer but the history the softer consistency of the tumor the presence of hydatid thrill and the slower development without marked cachexia are differential points *Hepatic abscess* presents signs more characteristic of infection namely rigors and fever marked leukocytosis and sweats A history of amebiasis or a pyemic condition is common jaundice or ascites on the other hand are evidences of cancer *Portal cirrhosis* in its earlier stages may cause enlargement of the liver but the enlargement is more uniform on palpation there are evidences of portal obstruction with enlargement of the spleen the disease progresses slowly and the liver tends to decrease in size *Biliary cirrhosis* occurs in younger individuals the enlarged liver is smooth the spleen is enlarged the jaundice early and the course very chronic *Obstruction of the common bile duct with gallstone* causes changes resembling those of malignancy such as jaundice and enlargement of the liver with local pain and tenderness The enlargement however is usually slight, while the pain is paroxysmal and associated with chills and fever The jaundice tends to fluctuate and there is usually an antecedent history pointing to cholecystitis

Prognosis —As a rule malignant disease of the liver terminates fatally within from three to twelve months after enlargement of the liver has been noted The course of the primary is usually more rapid than that of the secondary type

Treatment is chiefly palliative Relief of pain is secured only by the use of morphine. This should be given in doses sufficient to keep the patient comfortable If the liver is very large a binder or supporting belt may be advantageously employed The appetite is improved to some extent by the ingestion of dilute hydrochloric acid (1 drachm with meals) and vomiting may be combated by the administration of bismuth dilute hydrocyanic acid or morphine The bowels should be regulated by salines For the itching calcium lactate 1 Gm (15 grains) three times daily may be given internally, and carbolic acid (1 60) or soda bicarbonate solution externally The hypodermic administration of atropine pilocarpine or morphine is sometimes helpful in obstinate cases Operation for removal of the tumor is rarely possible but when the growth is solitary such treatment may be justifiable

BENIGN TUMORS OF THE LIVER

Benign tumors of the liver are uncommon and are of little clinical importance *Hemangiomata* which are occasionally seen are as a rule small and situated just be-

Jaundice is often the outstanding sign of disease of the biliary tract The jaundice which is associated with abnormalities of the bile ducts is of the regurgitation type As Rich has pointed out regurgitation jaundice includes those cases in which bile gains access to the blood This group is characterized by a prompt van den Bergh reaction and the presence of bilirubin in the urine in contrast with retention jaundice in which bilirubin alone accumulates in the blood due to faulty excretion by the liver cells In the latter group which includes hemolytic jaundice and certain milder forms of liver damage the van den Bergh reaction is delayed or indirect and bilirubinuria is absent Regurgitation jaundice is often accompanied by varying degrees of pruritus while retention jaundice is not It may be emphasized that the two forms often occur simultaneously As an example cases of hemolytic jaundice complicated by common duct calculi may be cited The regurgitation jaundice resulting from stone cancer or stricture of the common bile duct is due to increased intrabiliary pressure So far as can be determined this results in rupture of many of the smallest bile ducts within the liver Bloom and others have shown that the bile escapes chiefly into the adjacent lymphatic spaces thence to the thoracic duct and circulating blood There is much experimental work which indicates that regurgitation of bile may also occur as a result of increased permeability of the small bile ducts particularly the ampullary portions of the bile capillaries This change in permeability is caused by a variety of poisons and toxins The jaundice which results may be spoken of as parenchymal in contradistinction to cancerous and calculous jaundice The term cancerous jaundice applies chiefly to biliary tract cancer (involvement of the main bile ducts) There are in addition certain forms of jaundice which are not readily classified with these three main groups such as common duct stricture pressure of benign tumors or cysts Hodgkin s disease or leukemia and parasitic disease All of the latter as well as the various types of parenchymal jaundice are classified from a fundamental standpoint as members of the regurgitation jaundice group but from the standpoint of prognosis and treatment particularly the question of surgery, it is essential that parenchymal jaundice be distinguished from that due to common duct stone cancer of the bile ducts and other extrahepatic biliary tract disease This distinction is at times exceedingly difficult, and may depend upon correlation of data gained in a number of different ways including microscopic study of bile obtained by duodenal drainage (Lyon) study of the degree of biliary obstruction as determined by urobilinogen excretion (Watson) and investigation of liver function by various methods such as determination of the urine urobilinogen galactose tolerance serum proteins cholesterol hippuric acid test and others Cholecystography as devised by Graham and Cole is often of decisive importance in cases without jaundice while in patients with considerable jaundice the procedure is of little or no value and is not recommended

CHOLELITHIASIS

(*Gallstones Biliary Calculus*)

Etiology and Occurrence—The majority of human gallstones are composed chiefly of cholesterol The concentration of cholesterol in the bile as well as its stability of solution is therefore of much significance Several important factors may be mentioned

Concentration of Bile—The bile is concentrated from five to ten times in the gall bladder and the degree of concentration is increased when the rate of emptying is relatively slow During pregnancy for example gallbladder function is distinctly sluggish (Boyden) with the result that stasis and further bile concentration are favored

from *cirrhosis passive congestion leukemic infiltration amyloid disease* and *displacements*

Treatment —The treatment is that of the primary or causative condition

Amyloid Liver (*Waxy or Lardaceous Liver*) —Amyloid disease of the liver is not common in the United States and Canada It occurs as part of a general degeneration, which is usually most marked in the spleen and kidneys The disease most often attacks young people, usually as the result of long continued tuberculous or other suppuration or of syphilis Occasionally it follows such wasting diseases as cancer anemia, chronic arthritis, and other chronic infections In syphilitic cases there is often tertiary ulceration, but amyloid disease may occur without suppuration The view that it is of toxic origin is supported by suggestive results of experiments in which animals were injected with products of pyogenic bacteria or other toxic substances Probably modern methods of treatment, by reducing the incidence of prolonged suppuration are responsible for the relative infrequence of amyloid disease at the present time

Morbid Anatomy —The amyloid liver is uniformly enlarged and in some cases attains four or five times its original size It is smooth firm and cuts with resistance The cut surface is pale and semitranslucent Stained with Lugol s solution the tissue appears rich mahogany brown in the amyloid areas The median portions of the lobules are affected first the process spreading both centrally and peripherally as the disease advances Microscopically it can be seen that homogeneous amyloid material is deposited in the capillary walls external to the endothelial lining In more advanced cases there is also a deposit about the small branches of the hepatic artery

Symptoms —On clinical examination the liver is found to be uniformly enlarged and smooth but there is no pain or tenderness The patient complains of no symptoms directly referable to the liver unless the enlargement is so great as to cause discomfort in the hepatic area Symptoms of the primary or associated disease are usually present however and include general debility wasting and a pale cachectic appearance The spleen is nearly always enlarged and firm, but there is no ascites Jaundice does not occur

Diagnosis —The history of antecedent or associated disease of a nature likely to caus amyloidosis, and the finding of an enlarged smooth firm, and painless liver and spleen should suggest the diagnosis In the presence of such findings, a positive Congo red test would strongly support the diagnosis The condition must be differentiated from *fatty liver cirrhosis passive congestion leukemic infiltration and displacement*

Treatment —The treatment is that of the disease giving rise to the amyloid change There are no remedies specific for the hepatic lesion The development of amyloidosis of the liver does not affect the prognosis of the case except that to some degree it is an index of the extent of the general disease

DISEASES OF THE GALLBLADDER AND BILE DUCTS

INTRODUCTION

The central point of interest in this group of diseases is cholelithiasis Gallstones are the most frequent source of symptoms referable to the biliary tract They are commonly related to the development of a variety of abnormalities such as cholangitis, liver abscesses jaundice and biliary cirrhosis Furthermore they are of undoubted significance in the etiology of primary cancer of the gallbladder and ducts The early recognition of gallstones is therefore a matter of considerable importance Modern methods including cholecystography and microscopic examination of bile obtained by duodenal drainage have aided greatly in the diagnosis The history and physical examination however remain indispensable and often sufficient in themselves to suggest strongly the presence of cholelithiasis

which no symptoms had been noted during life This fact makes it difficult to establish the time of formation of gallstones and impossible therefore to correlate them with age in any exact way

Sex—From 5 to 10 per cent of adults of both sexes are found to have gallstones at autopsy Chiefly because of pregnancy perhaps also because of dietary factors obesity and sedentary habits the percentage is much higher among women than men and is probably in the neighborhood of 20 per cent of women who have borne children

Diet—No definite relationship is known although it is true that gallstones are somewhat more common in obese individuals It may be true that overeating particularly of fats is important to the genesis of gallstones because of hypercholesterolemia The relatively rare occurrence of gallstones among Oriental people suggests that differences in diet may be of considerable importance

Variety and Character of Biliary Calculi—Numerous classifications of gallstones have been suggested of which the simplest and most useful especially from a clinical standpoint appears to be that which depends on whether the stone is relatively pure in composition or a distinct mixture of two or more substances On this basis gallstones may be subdivided as follows (1) Pure stones either cholesterol calcium bilirubinate or calcium carbonate (2) Mixed stones including a preponderance of cholesterol together with one or more of the other materials just referred to as well as albuminate cellular debris and occasionally foreign bodies such as fragments of worms. Bacteria especially viable typhoid bacilli, may be included (such individuals are not

Fig 80—*a* Solitary cholesterol stone in dye-filled gallbladder *b* Displacement of stone into neck of gall bladder after contraction due to fatty meal (Courtesy of Dr Leo G Rigler)

Cholesterol Content of the Bile—Hypercholesterolemia has been shown to be associated with an increased quantity of cholesterol in the bile During the latter months of pregnancy and for a time after delivery, hypercholesterolemia is marked This, together with biliary stasis as mentioned above is probably important to the definite correlation that is known to exist between pregnancy and gallstone formation Hypercholesterolemia alone cannot be said to produce gallstones since there are a number of diseases, such as myxedema and nephrosis exhibiting hypercholesterolemia, but in which cholelithiasis is no more common than in the normal population Cholesterol is maintained in solution in the bile at least in part, because of the presence of bile salts It is probable that significant reduction in bile salt concentration tends toward precipitation of cholesterol The concentration of bile salts and cholesterol in the bile depends in part on the normal function of the liver cells In conditions associated with hepatocellular damage the concentration of both the bile salts and cholesterol tends to diminish This may explain the fact that gallstone formation has not been correlated definitely with parenchymal liver disease such as due to various poisons and infections Nevertheless since gallstones may be present for long periods without manifestations it is impossible to be certain that some previous toxic effect on the liver was not responsible for the onset of stone formation due to a temporary lowering of bile salt concentration in the bile There undoubtedly are instances of liver damage in which the bile salt concentration is relatively much lower than that of cholesterol

Infection—Naunyn believed that infection preceded all gallstones He pointed out that stasis is usually preliminary to infection The importance of infection to gallstone formation is as follows (1) the fact that small masses of exudate (leukocytes fibrin epithelial cells) serve as nuclei around which precipitation of cholesterol and other substances takes place Precipitated albumin favors the precipitation of calcium bilirubinate either in crystalline or amorphous state Infection is probably the chief factor in the formation of multiple gallstones in contradistinction to the solitary, large cholesterol stones which are usually regarded as metabolic and noninfectious in origin According to Aschoff the latter commence with the precipitation of cholesterol on some one occasion and any subsequent precipitation results simply in an increase around the solitary nucleus After infection however, there are multiple nuclei about which subsequent precipitation may take place. The equal growth around multiple nuclei accounts for the fact that the gallstones in any one gallbladder are commonly of the same general size (2) Infection alters the bile salt cholesterol ratio in the bile So far as can be determined at present this is due to two factors Infection probably accelerates bile salt reabsorption from the mucosa of the gallbladder Infection tends to decrease the bile salt concentration because of suppression of liver cell activity Whether infection has any influence on cholesterol concentration is unknown Chauffard believed that the frequency of gallstones after typhoid fever was related to hypercholesterolemia It appears however that biliary stasis, toxic suppression of bile salt formation and multiple exudative nuclei are equally, or even more important factors Gallstones from patients who have had typhoid fever not uncommonly contain viable typhoid bacilli

Bilirubin Concentration—In conditions associated with a marked and prolonged increase in the amount of bilirubin excreted in the bile such as hemolytic jaundice and pernicious anemia there is a distinct tendency for bilirubin to precipitate as the calcium compound

Calcium Carbonate—Phemister has emphasized the fact that obstruction of the cystic duct by one of the common variety of stones or by carcinoma may be followed by precipitation of calcium carbonate either in the form of a stone a cast of the gall bladder or a soft milky suspension

Predisposing Factors—*Age*—Clinical manifestations of gallstones are observed much more commonly after the age of forty although they are frequently encountered in younger women who have had one or more pregnancies While it is probable that gall stones usually produce symptoms within a few months after their formation there are many instances encountered at autopsy in

ance of persistent jaundice Chills and high fever may not be observed in these cases although a low grade temperature elevation is not uncommon

Physical examination reveals an enlarged liver firm and finely roughened particularly if the jaundice is of long duration At the operation this is found to represent a mild degree of cirrhosis of biliary or obstructive type The spleen is palpable with considerable frequency but not markedly enlarged Ascites occurs rarely Esophageal varices and hematemesis have been noted occasionally, but in such instances the question arises as to whether the cirrhosis was not coincidental and primary rather than secondary to calculous biliary obstruction Biliary or obstructive cirrhosis is undoubtedly related not only to chronic biliary obstruction but perhaps more closely to biliary tract infection associated with calculi Graham has noted the association of cirrhosis with gallstones and biliary infection in individuals who had not been jaundiced

Gallstone Colic (Biliary Colic Hepatic Colic) —Attacks are usually abrupt in onset often commencing several hours after a heavy meal and as a consequence most often occurring in the evening or during the night The colic is due to smooth muscle spasm or stretching of either he gallbladder or ducts The stone may be in the cystic or common duct and the onset of colic follows shortly upon migration of the stone to a new location either from the gallbladder to the cystic or common bile duct or from the dilated common duct into the ampulla The intensity of the colicky pain is variable in different attacks and depends in some degree upon the patient s sensitivity to pain In general the attacks are of a severe nature causing the patient to writhe roll or double up to walk about in anguish to press his fists into his abdomen or to shout or cry because of acute distress In many cases these symptoms are accompanied by profound sweating The pain is located in the right upper quadrant of the abdomen at times somewhat near the midline From the site of onset it radiates through to the back usually beneath the right scapula and sometimes to the right shoulder The duration of the attack is variable rarely more than several hours often less Vomiting is usual and in many instances brings some degree of relief In some cases the attacks recur very frequently in others after an intermission of months or even years Fever and leukocytosis may or may not occur depending upon the presence and degree of infection in the gallbladder if there is a stone in the cystic duct or in the bile ducts if the stone is in the common duct Slight or moderate icterus may be noted The urine often contains bilirubin within a few hours after the attack This is a regular occurrence with common duct calculus and is the basis for the important history of temporarily dark urine The stools are often light in color for from one to several days

Complications —Internal biliary fistulae may open into the colon duodenum or rarely the pylorus also into the peritoneal or pleural cavities and the skin Cholecystoduodenal fistulae permit passage of large stones into the small bowel where they may produce intestinal obstruction This is characterized by an irregular recurrence of vomiting and abdominal distention as the stone moves slowly along the small bowel stopping at intervals until propelled further by increased peristalsis

There are other complications in which both gallstones and associated infection play a common role *i e* pancreatitis both acute and chronic peritonitis due to perforation of the gallbladder cholangitis and liver abscesses pylephlebitis rarely thrombosis of the hepatic vein or endocarditis

Diagnosis —The dyspeptic symptoms due to stones in the gallbladder must be distinguished from those of *peptic ulcer* Relief from food milk or soda is rarely noted to any distinct degree in cases of gallstones but is fairly characteristic of ulcer The distress of ulcer is usually located in midepigastrium while that due to gallstones is as a rule in the right upper quadrant of the abdomen Dull pain caused by an irritable *spastic colon* may be noted at times in the area of the gallbladder this is usually distinguished on the basis of the history of marked constipation or diarrhea relief of distress following bowel movement and the occurrence of pain at other times in the region of the cecum splenic flexure or sigmoid colon Spastic colon and gallstones may be present in the same individual and

necessarily infective carriers) In the mixed stones, the proportion of the different chemical components is quite variable in different cases cholesterol nearly always predominating to a marked degree Calcium may be deposited as a shell about a stone composed of cholesterol and calcium bilirubinate This is especially true in cases of cystic duct obstruction due to another stone Such stones are distinctly radiopaque Stones containing calcium bilirubinate are more difficult to visualize by x ray, while pure cholesterol is not distinguished except under optimal conditions by contrast with the dye used in cholecystography

Symptoms and Signs—The symptoms of gallstones are dependent in considerable measure upon their location Stones in the gallbladder probably produce symptoms by virtue of pressure or irritation of the wall of the viscus Colicky pain such as characterizes stones in the ducts is not produced Vague sensations of fulness dull distress in the epigastrium or right upper quadrant, especially after eating, also pyrosis sour eructations and flatulence are very suggestive of gallbladder stones Distress is often more noticeable after certain foods are eaten notably pork cabbage, or fried foods Other individuals however with proved gallstones, may not observe any qualitative food distress The amount of food may or may not be of significance, in various instances although it is commonly noted that attacks follow a heavy meal During pregnancy the symptoms are usually exaggerated presumably because of increased biliary stasis

The physical signs of gallbladder stones are few or none There may or may not be tenderness over the region of the gallbladder Rarely it is possible to palpate such stones especially if they compose a large mass adherent in the fundus of the thickened gallbladder

Stones occluding the cystic duct commonly produce biliary colic as described below The gallbladder is often distended at times enormously so with a thin watery mucus This distention is in contrast to the small or 'atrophied' gallbladders usually noted in patients having common duct stone (Courvoisier) Chronic cystic duct obstruction may result in "hydrops" of the gallbladder of such extent that even several liters of fluid are found in the viscus at operation or autopsy, and in these cases it may extend well down into the pelvis Of greater danger, however, is the accumulation of purulent exudate in the obstructed gallbladder This condition of empyema may result in gangrene and perforation with generalized peritonitis The gallbladder under these circumstances may dilate considerably even though the wall is markedly thickened This is simply because of the considerable increase in intraluminal pressure plus inflammatory softening of the gallbladder wall A further discussion of this condition is found below under the heading of acute cholecystitis

Stone in the Common Duct—More often than not common duct calculi are multiple Pain is produced when the stone or stones first enter the duct, following which there is stretching and smooth muscle spasm in an attempt to expel the stone As the duct dilates colic may disappear until such time as a stone enters the ampulla of Vater when smooth muscle contraction again produces pain which is often intermittent as the stone moves up and down in the lower end of the duct A ball valve action of this type usually results in jaundice of fluctuating intensity and is often productive of suppurative cholangitis with chills and fever The latter has been spoken of as 'hepatic intermittent fever (Charcot Osler) The fever abates when bile drainage is reestablished and recurs as the stone reenters the ampulla Disappearance of fever and jaundice is usually not due to expulsion of the stone through the ampulla More often this is simply due to a shift in position of the stone within the duct Expulsion occurs at times however and in these cases the stone may be recovered from the stools Except where the diagnosis of cholelithiasis is in doubt examination of the stools for gallstones has relatively little value since the finding of a stone gives no clue as to how many remain in the common duct or gallbladder In doubtful cases the stools should be strained for stones after repeated duodenal instillation of magnesium sulfate (See later)

Stones Impacted in the Ampulla of Vater—This condition is characterized by chronic jaundice and as a rule marked pruritus Pain is often absent but there is usually a history of colicky pain prior to the appear

and Cole) If given in the evening x ray the following morning will reveal the shadow due to concentrated dye within the gallbladder A fatty meal or an egg yolk meal (Boyden) results in prompt contraction of the size of this shadow if the gallbladder function is normal If the cystic duct is occluded or if the gallbladder has entirely lost its concentrating function there may not be a sufficient concentration of dye to permit of contrast with cholesterol stones in this event the condition can be classified only as a non functioning gallbladder in which stones may or may not be present An upright film is occasionally of value in demonstrating cholesterol stones not otherwise evident In the upright position the stones may be concentrated in a layer near the fundus of the gallbladder Cholecystography is probably about 90 per cent efficient in the demonstration of gallstones Duodenal drainage (Lyon) is often confirmatory in doubtful cases it rarely yields positive information where x rays are negative although the converse is often noted (Doran)

Biliary colic is usually recognized without difficulty *Renal* and *intestinal colic* rarely cause confusion The pain of renal colic commences in the loin or flank and radiates downward especially to the inner surface of the thigh or to the genitalia dysuria and hematuria are often present The pain of intestinal colic (including lead colic and acute porphyria) is usually a more generalized crampy pain often somewhat more marked below the level of the umbilicus If due to intestinal obstruction there is increasing emesis distention of the abdomen and the auscultatory finding of high pitched or musical borborygmi in association with the colicky pain If due to *lead colic* the occupational history the presence of a lead line on the gums and the finding of basophilic stippling in the red blood cells are all of aid in diagnosis The colic of *acute porphyria* may closely simulate gallstone colic the presence of red urine due to porphyrin (or of urine that becomes red on exposure to light) is of decisive importance

The pain of acute *coronary thrombosis* may be confused with that due to gallstones In some cases coronary thrombosis is productive of abdominal distress only and this may be limited to the right upper quadrant or epigastrium The electrocardiogram is of much aid in such instances The presence of a pericardial friction rub is distinctive. Slight jaundice may follow an attack of coronary thrombosis but is less common than with biliary calculus and does not appear as a rule until several days after the attack when it is often but not always associated with pulmonary infarct Jaundice and dark urine (bilirubinuria) usually appear within twenty four hours after a gall stone colic if at all Urobilinogenuria is usually noted shortly after a gallstone attack but is delayed for from forty eight to seventy two hours following a coronary thrombosis *Biliary dyskinesia* (or dyssynergia) without gallstones is undoubtedly productive of biliary colic in rare instances This term indicates a simultaneous spastic contraction of the gallbladder and sphincter choledochus with resultant colicky pain The cause of the condition is not clear There can be little doubt that persistent distress after cholecystectomy especially where stones were not found is at times due to recurrent spasm of the sphincter of Oddi Biliary dyskinesia is recognized by the fact that cholecystokinin or substances such as egg yolk which stimulate its production cause spasm of the sphincter of Oddi With the duodenal tube in position no bile can be obtained but after instillation of magnesium sulfate dark bile appears and the pain promptly abates (Ivy) Dyskinesia is not to be considered unless gallstones have been excluded by all possible means

Marked jaundice due to *impacted stone* is at times confused with jaundice due to cancer of the biliary tract including carcinoma of the head of the pancreas A previous history of gallstone colic and jaundice is suggestive of calculous jaundice but it must be borne in mind that cancer of the bile ducts is relatively common in individuals with gallstones Loss of weight is usually more profound in the presence of cancer of the biliary tract than in jaundice due to stone The following features are of particular aid in distinguishing these conditions (1) The presence of complete biliary obstruction as denoted by the finding of less than 5 mg of fecal urobilinogen per day with less than 0 3 mg of urobilinogen in the twenty four hour urine This finding is

there is little doubt that gallstones aggravate irritability of the colon

Gallbladder stones are but rarely palpable and even in such instances, diagnosis must be confirmed by x ray Palpable stones usually contain enough calcium to permit visualization by means of a simple flat plate of the gallbladder region Cholecystography is often necessary for the diagnosis of gall stones particularly those composed chiefly of cholesterol with little or no calcium This method depends simply upon excretion of tetraiodophenolphthalein by the liver into the bile with subsequent concentration in the gallbladder The dye may be given by mouth quite satisfactorily It is absorbed into the portal circulation and about 96 per cent of it is excreted in the bile (Graham

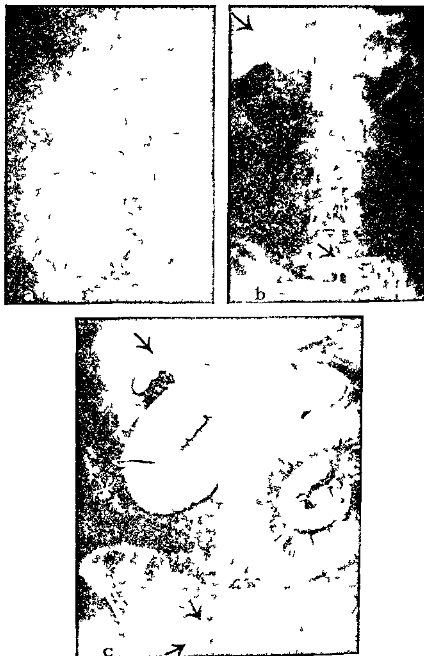

Fig 81 —*a* Mass of calcified gallstones in the gallbladder as noted on 7/22/31 *b* 8/18/32 Patient now has symptoms of bowel obstruction Upper arrow indicates gas in the biliary ducts (due to cholecystoduodenal fistula) Lower arrow indicates the mass of calcified gallstones now in the small bowel *c* After barium meal upper arrow indicates cholecystoduodenal fistula Lower arrows indicate gallstones in the small bowel. Note distended loops above (Borman and Rigler Surg 51 1937)

tapioca later vegetables Baked or mashed potato spinach carrots, string beans asparagus lettuce celery squash are tolerated best Onions sauerkraut cabbage turnips radishes or cucumbers may cause recurrence of distress Lean meat including roast or boiled chicken beef or lamb may be eaten in moderation Baked or boiled fish is usually tolerated Butter and cream should be taken but sparingly, vegetable fat particularly olive oil probably has a beneficial effect in stimulating bile flow without being productive of distress

Bile salts are distinctly beneficial They should be used in fairly pure form not simply as dehydrated bile which may induce nausea and distress Given in an amount of 3 to 6 grains (0 2–0 4 Gm) three times daily bile salts often appear to prevent recurrences of symptoms for long periods of time Occasional cases have been observed in which multiple gallbladder stones disappeared after a long course of bile salt therapy

For relief of biliary colic nitroglycerin or amyl nitrite inhalations should first receive trial If nitroglycerin is used a tablet of hypodermic type $1/100$ grain (0 00065 Gm) is placed beneath the tongue and allowed to dissolve At the same time sodium phenobarbital 2 grains (0 13 Gm) may be given subcutaneously Prompt relief is often afforded by these measures In some cases it will be necessary to use morphine sulfate $1/6$ to $1/4$ grain (0 01–0 016 Gm) by hypodermic although there is little doubt that morphine increases spasm of the sphincter choledochus thus increasing intrabiliary pressure (Walters Bergh and Layne) While morphine has been employed for many years in the treatment of biliary colic and is still necessary in many instances its analgesic effect in these cases is central and not local and it is not improbable that the resulting increase in intrabiliary pressure is undesirable

Milder attacks of colic are at times allayed simply by rest the application of hot compresses to the abdomen and the evacuation of gas by means of a tap water enema

In cases of calculous jaundice repeated duodenal instillation of magnesium sulfate on three or four successive days is advisable The icterus may abate rapidly with the result that the patient is in better condition for operation

The treatment of pruritus associated with jaundice is not particularly gratifying Calamine lotion or carbolic lotion 1 60 are of aid in some cases If it is known that the patient is not sensitive to novocain very gratifying results are at times noted following intravenous administration of $1/6$ grain (0 010 Gm) or 10 cc of a 0 1 per cent solution At times this may be the only means of permitting the patient to sleep through the night

Surgical—Adequate preoperative preparation is of utmost importance This is particularly true in jaundiced patients The prothrombin time (Quick) should be determined and if significantly prolonged *vitamin K* together with bile salts are given If the prothrombin time is prolonged synthetic 2 methyl 1 4 naphthoquinone may be given either by mouth or intravenously This substance is even more effective than natural vitamin K which has the disadvantage of being insoluble in water There are several water soluble preparations of the synthetic naphthoquinone on the market which are entirely satisfactory It is unnecessary to use bile salts with these whereas this is essential with the natural fat soluble vitamin K Given by mouth an amount of 5 mg daily is adequate If given intravenously 1 mg of the active material per day suffices The response of the prothrombin time to intravenous injection is of considerable diagnostic and prognostic value In general it may be said that with relatively good liver function the prothrombin time will return to the control level within six hours after intravenous administration of 1 mg with poor liver function especially with primary diffuse liver damage the prothrombin time is unlikely to return to the normal range

Operations on the biliary tract should be preceded by a diet plentiful in protein and carbohydrate and low in fat In general this diet should consist of approximately 300 Gm of carbohydrate 100–150 Gm of protein and a minimal amount of fat (30–40 Gm) If the patient is unable to eat a regular diet it may nevertheless be possible to give frequent liquid feedings consisting of skim milk fortified with a powdered food of

noted in over 90 per cent of cases of cancer of the biliary tract and in less than 10 per cent of the cases of calculous jaundice (Watson) (2) The palpation of a smooth nontender distended gallbladder This is frequently possible in cases of cancer of the biliary tract, but rare in jaundice due to stone in the common duct Courvoisier found that the gallbladder was atrophied in 70 of 87 cases of calculous jaundice, as contrasted with 17 in which it was dilated This dilatation was marked in but 2 cases These figures related to observations at operation or autopsy The clinical value of palpating a distended gallbladder is probably even greater than Courvoisier's figures indicate In the writer's experience, a distended gall bladder of the type mentioned above has not been palpated in cases of jaundice due to calculus in the common duct When found in association with complete biliary obstruction the diagnosis of cancer of the biliary tract is relatively certain

Parenchymal jaundice may be confused with calculous jaundice The term parenchymal applies to diffuse cellular liver damage such as occurs with cirrhosis acute or subacute atrophy and in many cases of so called 'catarrhal jaundice In distinguishing jaundice due to *cirrhosis* the following features are of importance the history of chronic alcoholism of ingestion of drugs such as cinchophen or arsenic of arsenical therapy for syphilis or of a previous attack of painless jaundice the presence of a small liver with or without ascites the development of collateral circulation over the abdomen enlargement of the spleen hematemesis and demonstration of esophageal varices by x ray, the presence of *spider nevi* in the areas of the body drained by the superior vena cava In *acute atrophy* the outstanding differential features are progressive increase of painless jaundice, demonstrable decrease in the size of the liver early appearance of somnolence and coma the 'fetor hepaticus or amine odor a peculiar musty sweetish and very pervading aromatic odor quite characteristic of diffuse necrosis of the liver (Eppinger) This odor is noted at times in cases of advanced cirrhosis of the liver, and has also been observed in lesser degree in occasional cases of protracted severe catarrhal jaundice The latter condition is distinguished from calculous jaundice by virtue of the absence of colic the characteristic urobilinogenuria which often disappears briefly at the height of the icterus, then reappears rapidly and in marked degree as convalescence begins the positive galactose tolerance test A negative result of the galactose test is without significance however, especially after the jaundice has been present for more than a few days

Prognosis —Cholelithiasis of itself is rarely fatal but death may be caused by complications such as perforation of the gallbladder cholangitis liver abscesses or acute pancreatitis

Treatment —The choice of medical or surgical treatment of gallstones depends chiefly on the patient's general condition as well as on his or her wishes in the matter Cholecystectomy is the procedure of choice in cases where the presence of gallstones is proved Operation should not be undertaken simply because of pain presumed to be due to gallstones or gallbladder disease Operation may be deemed inadvisable in proved cases because of advanced age cardiac failure renal insufficiency or other serious disease In the usual case however cholecystectomy is indicated because of the many serious complications which gallstones may produce Cases of cholelithiasis when not treated surgically are apt to have recurrent attacks in spite of medical management operation has often been postponed until some dangerous complication has appeared and the patient may now have reached an age which in itself materially increases the risk Furthermore the important relation of cholelithiasis to the occurrence of primary cancer of the biliary tract must be taken into account

Medical —Control of the diet is of prime importance Foods high in cholesterol such as fat and eggs should be eliminated or greatly reduced Greasy or fried foods pork products rich dressings and cheese spicy foods, and alcoholic beverages are most likely to cause exacerbation of symptoms Immediately after an acute attack it is desirable that the diet be limited to liquids such as skim milk milk soups and strained orange juice in small amounts After a short time cereals may be added then rice and

CHOLECYSTITIS

Etiology —The age and sex incidence parallels that of cholelithiasis except in typhoid epidemics in which acute cholecystitis may occur in children of both sexes It is probable that acute cholecystitis is usually infectious in origin less often chemical This is still a matter of dispute The acutely inflamed gallbladder however does not always contain demonstrable bacteria (Andrews) Regurgitation of pancreatic juice into the biliary tract may at times play a role The large majority of cases of acute cholecystitis are associated with cholelithiasis and it is probable that gallstones are of much importance both from the standpoint of obstruction and stasis as is trauma to the mucosa

Acute cholecystitis may occur without gallstones This is noted particularly as a complication of about 1 per cent of cases of typhoid fever but may also be encountered in the wake of other acute infections

Members of the colon typhoid group are found most commonly when the contents of the acutely inflamed gallbladder are cultured The staphylococcus pneumococcus or streptococcus are present much le s frequently It is probable that these organisms gain access to the gallbladder either by way of the blood stream or by ascent from the duodenum Statistics as to which is the most frequent route are not available

Chronic cholecystitis is to be regarded as the quiescent stage of the disease after subsidence of acute manifestations Subsequent acute attacks are apt to occur There is usually but not always an associated cholelithiasis

Morbid Anatomy —Acute cholecystitis varies in degree from a mild catarrhal type to an extremely dangerous phlegmonous or gangrenous form In the mild catarrhal form the gallbladder is often moderately distended the serosa exhibits injection of the blood vessels the wall is somewhat tense and swollen and the mucosa is congested at times revealing small amounts of fibrinopurulent exudate on its surface Microscopically congestion and a moderate exudation of polymorphonuclear leukocytes in the submucosa and outer coats are observed

Fig 82 —*a* Cholangiogram taken with T tube in common bile duct Arrow indicates residual stone in lower end of duct *b* After removal of stone at a secondary operation (Courtesy of Dr Leo G Rigler)

The *phlegmonous* type is characterized by marked thickening of the gallbladder wall at times attaining more than 1 cm As a rule the cystic duct is obstructed by stone and the resulting pressure within the gallbladder is sufficient to cau e distention which may be considerable in some cases The increase in pressure plus softening of the wall or outspoken gangrene constitute the chief dan

high protein and carbohydrate content Foods of this type are available which contain 35–40 per cent protein and 60–65 per cent carbohydrate and which are at the same time rich in minerals and added vitamins When mixed with skim milk a food value of 1000 calories per liter or more can be attained The studies of Ravdin and of Whipple and his associates reveal clearly that an adequate intake of protein is essential to the protection of the liver While there is no doubt that glucose is of value, it is quite insufficient in many instances to prepare patients for operation simply by giving them intravenous glucose as is often customary This is especially true if the patient is malnourished febrile toxic or markedly obese Such individuals are apt to have fatty livers a factor of great importance in operative mortality The amount of glucose that is given intravenously is often not enough to supply the patient s caloric needs much less to convert the fatty liver into one filled with glycogen Further than this the preoperative preparation should include if at all possible a plentiful supply of vitamins especially B complex Choline and riboflavin deficiency in particular have been implicated with respect to fatty infiltration of the liver It is probably best to give these patients crude sources of B complex either brewer s yeast in amounts of 30–40 Gm daily or relatively crude liver extract fortified with the known components such as thiamin niacin and riboflavin The dosage of such preparations is empirical but it should probably not be less than 8 or 10 capsules daily

Cholecystectomy in cases of proved gall stones effects a cure in most instances The operative mortality rate is very low in the hands of experienced surgeons usually not exceeding 1 5 per cent The fatality figure is higher for operations on the common duct

Secondary operations are necessary at times because of postoperative stricture unrecognized common duct stone reforming of stones in the hepatic or common bile ducts adhesions or hernia Common duct calculi are apt to be overlooked unless the common duct is opened and explored This should be done if the patient is or has been jaundiced assuming that operation has been decided upon If possible it is wise to have a cholangiogram made at the time of operation, before the abdomen is closed After stones have been removed from the duct, T-tube drainage should be carried out for a period of months Before the T tube is removed from the duct a *cholangiogram* should again be made This consists of injecting a radiopaque material usually 50 per cent diadrast, into the T tube then taking an x ray film of the area of the common duct and ampulla Cholangiograms at times reveal unsuspected stones which were overlooked at operation in spite of opening the common duct Best has described procedures intended to expel these stones into the duodenum These include the injection of magnesium sulfate solution and of olive oil into the T tube also the use of nitroglycerin

Failure of cholecystectomy to relieve symptoms is much more common in cases where gallstones were not demonstrated either before or during operation Some of these cases at least belong in the *biliary dyskinesia* group

in the right lower quadrant rarely higher usually serves to distinguish appendicitis Right *pyelonephritis* at times simulates cholecystitis with respect to pain The maximal tenderness however is usually in the loin and this fact plus the urinary symptoms and findings make differentiation possible

Prognosis—Except for complications such as perforation and peritonitis pancreatitis or liver abscess the chances for immediate recovery are excellent Subsequent attacks however are likely to occur

Treatment—In the milder forms rest in bed liquid diet heat to the abdomen, and sedatives usually result in rapid disappearance of symptoms In the more severe forms the question of surgical intervention is often a difficult one Some believe that cholecystectomy should be performed in the early stage of every case of acute cholecystitis In general however it is probably wiser to adopt conservative measures at the outset since the large majority of cases respond well and operation may then be carried out with relative safety during a quiescent stage After the acute symptoms have subsided it is desirable to wait several weeks before surgery is undertaken If conservative measures fail to bring some degree of improvement within two to three days and the severity appears to be such that perforation is feared the procedure of choice is cholecystostomy Extirpation of distended empyematous gallbladders is not advisable In older individuals where circulatory complications are often present it may be possible simply to drain the gallbladder under local anesthesia Later depending upon the patient s general condition cholecystectomy may be indicated

Conservative measures during the acute stage include hot moist compresses to the abdomen sedation by means of sodium phenobarbital subcutaneously (2 grains [0 13 Gm] at intervals of four to six hours) and morphine 1/6 to 1/4 grain (0 01–0 016 Gm) if necessary to relieve severe distress Nasal suction siphonage may be necessary for abdominal distention and vomiting In the severer cases nothing other than ice chips should be given by mouth Infusions of 5 per cent glucose in saline may be administered subcutaneously and intravenously As the attack subsides liquids by mouth may be started and the diet as already described under the treatment of gallstone colic may be instituted

The treatment of chronic cholecystitis depends on several factors the most important of which is the presence of gallstones If these are demonstrated cholecystectomy is usually the procedure of choice This will depend again upon the patient s age and general condition the operation should not be carried out in the presence of any serious constitutional disease such as myocardial or renal insufficiency If there have been repeated distinct attacks of acute cholecystitis even though stones cannot be demonstrated cholecystectomy is usually indicated during a quiescent period Conservative treatment is to be preferred however in patients who complain only of dyspeptic symptoms and in whom the cholecystogram has revealed nothing more than a reduced gallbladder function There can be no doubt of the rare occurrence of mild chronic cholecystitis with apparently normal gallbladder function as determined by cholecystography The symptoms in these cases are probably often on the dyskinetic basis although there is good evidence that biliary dyskinesia also exists without any demonstrable pathologic change in the gallbladder or ducts The results of operation in this group of cases are usually disappointing Distress frequently recurs Conservative treatment consisting of the diet already suggested for the management of cholelithiasis together with bile salts often enables the patient to avoid distress The use of magnesium sulfate is at times beneficial probably because of its relaxing effect on the sphincter of Oddi

gers of this disease, i e perforation and peritonitis This occurs with relatively greater frequency in patients more than sixty years of age The inflammation in most cases subsides without perforation If the cystic duct remains closed the distention of the gall bladder may persist either as a low grade or subsiding empyema, or a hydrops

In phlegmonous or acute suppurative cholecystitis, microscopic examination shows a very diffuse exudate throughout the entire wall composed of polymorphonuclear leukocytes and fibrin Necrosis may be noted and is prominent in the gangrenous type In chronic cholecystitis perivascular foci of lymphocytes are seen in the serosa there is often moderate thickening of the gall bladder wall with some increase of connective tissue and extensive adhesions to adjacent organs *Cholesterosis* or straw berry' gallbladder may be secondary to low grade subacute or chronic inflammation In this condition, cholesterol esters are deposited just beneath the mucosa and are seen grossly as numerous yellowish granules or streaks The exact nature of cholesterosis is as yet unknown

Symptoms and Signs—The symptoms of chronic cholecystitis cannot be distinguished from those of stones in the gallbladder The manifestations of acute cholecystitis are in proportion to its severity In the mild catarrhal form there may be nothing more than indigestion moderate pain and tenderness in the right upper quadrant of the abdomen slight fever and malaise With more severe degrees of infection there is more marked pain and tenderness and muscle spasm is elicited Rebound tenderness in the right upper abdomen is noted in the more severe cases of suppurative cholecystitis The spread of pain tenderness and rebound tenderness over the abdomen generally indicates either that perforation has occurred or that there is an associated pancreatitis with areas of fat necrosis in the omentum and mesentery The gallbladder is at times palpable in acute cholecystitis As a rule it is rather vague and difficult to outline principally because of tenderness and muscle spasm At times however the gallbladder is felt more distinctly as a very tender sausage like mass extending down below the right rib margin slightly lateral to the midclavicular line This type is more often palpated in patients suffering their first attack of cholecystitis where there has not been previous thickening of the gall bladder wall for example with typhoid fever

Marked prostration often results from acute suppurative cholecystitis The mouth temperature is commonly elevated to from 102° to 104° F Nausea and vomiting are frequently observed Abdominal distention (ileus) is not uncommon Jaundice may be present and if at all prominent indicates calculous obstruction of the common duct or the hepatic ducts Slight jaundice is due in some cases to associated liver damage which results from the infection spreading via the lymphatics into the liver The urine commonly contains increased amounts of urobilinogen which usually disappear within twenty four to forty eight hours after the infection subsides As a rule the attack of cholecystitis is of relatively short duration from a few hours to a few days In some instances however, empyema of the gall bladder may produce persistent pain and tenderness for weeks A somewhat vague tender mass representing the subacutely inflamed gallbladder may be felt for an equal period of time eventually becoming smaller and less tender, until finally it is no longer palpable During the stage of acute inflammation, the leukocyte count is elevated to from 12 000 to 40 000 usually about 15 000 This is a neutrophilic leukocytosis It is often of value in determining the severity of the infection particularly with reference to the question of operation, to follow the percentage of band forms or the filament nonfilament ratio

Diagnosis—The location and character of the pain and the history of previous attacks of gallstone colic or jaundice are helpful in distinguishing cholecystitis from *ulcer* After perforation has occurred the symptoms and findings may be identical The presence however of free gas in the peritoneal cavity, as determined by x ray is more likely to indicate perforation of the gastro intestinal tract rather than of the gallbladder *Acute appendicitis* particularly in individuals with a high lying cecum may offer difficulty The history of onset of diffuse abdominal pain with subsequent localization

CARCINOMA OF THE GALLBLADDER AND BILE DUCTS

Etiology and Occurrence—Carcinoma of the gallbladder is usually associated with gallstones and is consequently observed more frequently in females Carcinoma of the bile ducts is slightly more common in males nevertheless gallstones are not infrequently associated with this condition In general there can be little doubt that chronic irritation due to gallstones and associated infection is an important factor in the initiation of cancer of the gallbladder and to a lesser degree of the bile ducts

Morbid Anatomy—Carcinoma of the gallbladder may originate in any part of the viscus If primary in the fundus direct extension into the liver is common tumors primary in the corpus or collum often invade the bile ducts These differences in origin are of importance with respect to the presence or absence of icterus also to the type of mass palpable in the gallbladder area during life Tumors primary in the collum may cause simple distention of the gallbladder while tumors of the fundus are often responsible for a hard nodular mass Of interest is the fact that the gallbladder may be found to be markedly distended if the cystic duct is obstructed by a tumor This is quite comparable to what has already been discussed in connection with calculous obstruction of the cystic duct although the inflammatory changes with cancer are usually much milder in these cases the lumen of the gallbladder is filled with thin white mucus In some instances carcinoma obstructing the cystic duct may bleed into the lumen of the gallbladder thus causing marked distention Microscopically the tumor may be either carcinoma simplex adenocarcinoma or squamous cell carcinoma (metaplasia)

Carcinoma of the bile ducts is often of the scirrhous type and may be so small as to be confused with a benign fibrous stricture Microscopic examination in such instances reveals nests of cancer cells interspersed with fibrous tissue Suppurative cholangitis is seen at times above a primary carcinoma of the common duct or of the cystic duct at its junction with the common hepatic duct Primary carcinomata are relatively frequent at this point They may also occur in the lower end of the common duct In rare instances soft polypoid carcinomata occur within the common duct and may exhibit ball valve activity much like a stone in the common duct

Symptoms and Signs—Most of the cases have had previous symptoms of gallstones or cholecystitis Carcinoma of the fundus of the gallbladder produces dull constant pain and often tenderness weakness and loss of weight and a hard nodular mass in the region of the gallbladder Jaundice is usually present but may appear relatively late Once established it deepens progressively and complete biliary obstruction (less than 5 mg of fecal urobilinogen per day) usually occurs Jaundice appears relatively early with carcinoma of the corpus or collum of the gallbladder and it is usually the first symptom of primary carcinoma of the ducts In some instances the latter may be masked by the presence of colic chills and fever due to obstruction and cholangitis The jaundice occasionally disappears due to establishment of an internal biliary fistula

The liver may be enlarged and nodular with any of these primary carcinomata Enlargement due to metastases is somewhat more commonly encountered in cases of cancer of the gallbladder Ascites is noted at times due to peritoneal involvement As these conditions progress there is deepening jaundice cachexia and often a hemorrhagic tendency Somnolence and coma the cholemic state usually precedes death The hemorrhagic tendency is due at least in part to prothrombin deficit (prothrombin time often two to three times that of the normal control) The jaundice may be of a deep olive type this is said to be due to formation of biliverdin within the bile ducts for which oxidative ferments liberated from the tumor cells are held to be responsible Biliverdin icterus is strongly suggestive of carcinomatous biliary obstruction although at times it is seen in cases of jaundice not due to cancer

Diagnosis—The presence of *complete*

SUPPURATIVE CHOLANGITIS

Etiology and Occurrence —Suppurative *cholangitis usually results from biliary stasis* due to stone or neoplasm, in individuals who have had previous infection of the biliary tract The condition is observed most often with common duct calculus but is also seen at times with carcinoma of the gallbladder or bile ducts In the latter cases of cholangitis there is nearly always an associated cholelithiasis In contrast with these are the cases of carcinoma of the pancreas with biliary obstruction, in which cholangitis is relatively rare and in which there is usually not an associated cholelithiasis or previous biliary tract infection Various pyogenic organisms are responsible for suppurative cholangitis The colon bacillus and streptococcus are most common Very often these are present in the biliary tract prior to the onset of biliary stasis In other cases the infection of the obstructed bile ducts is probably hematogenous, although this is a matter of some doubt The occurrence of suppurative cholangitis in the absence of biliary obstruction is extremely rare

Morbid Anatomy —The bile ducts both intrahepatic and extrahepatic are dilated above the area of obstruction, which is usually in the common bile duct The ducts are also thickened because of inflammatory changes In the liver there is periportal inflammation often actually small abscesses *The periportal involvement is frequently of* chronic suppurative type in cases of cholangitis due to calculous obstruction Microscopically the small bile ducts are seen to contain polymorphonuclear leukocytes, and these are also found in variable number together with plasma cells and lymphocytes *in the adjacent portal areas*

The term 'cholangitis lenta' signifies a hematogenous form of suppurative cholangitis of grave prognosis due to a streptococcus Secondary endocarditis may occur (Pepper)

Symptoms and Signs —Jaundice with or without colicky pain chills and irregular but marked fever usually of spiking type are the outstanding features of suppurative cholangitis The liver is usually enlarged and moderately tender The spleen is occasionally palpable There is marked neutrophilic leukocytosis The urine contains bilirubin and as a rule much urobilinogen The blood culture may be positive

Complications —Metastatic abscesses may occur Hemorrhage from the mucous membranes is likely to result from prothrombin deficit, if this is not corrected by administration of vitamin K Hepatic coma is apt to precede death which is due to severe liver damage and insufficiency, together with generalized toxemia

Diagnosis —Suppurative cholangitis is likely to be present in any patient having jaundice chills fever sweating an enlarged tender liver, and leukocytosis especially if that patient has had previous jaundice or gallstone colics Liver abscesses due to other causes, and suppurative pylephlebitis may give rise to confusion The latter is suggested if there is free fluid in the abdomen The stools should be examined carefully for amebae in order to exclude amebic abscess *of the liver Duodenal drainage may establish* the presence of suppuration in the bile ducts

Prognosis —The prognosis is grave but not necessarily fatal If it is possible to establish adequate drainage recovery may occur

Treatment —Temporary spontaneous improvement not infrequently occurs particularly in the calculous cases in which obstruction is often partially relieved by the shifting position of a common duct stone It is *therefore best to support* the patient for several days with fluids and glucose parenterally The general condition may be improved by giving vitamins especially B complex and K (2 methyl 1 4 naphthoquinone) parenterally together with protein either in liquid form by mouth or as *plasma transfusions* Transfusion of blood is desirable if there is anemia or profound toxemia Operation should probably not be delayed for more than one week unless the infection is definitely subsiding At the end of this time T tube drainage of the common dust is usually advisable In some cases the surgeon may deem it sufficient to drain the gallbladder only if it can be established that the cystic duct is not obstructed

This subject is discussed in the section on Diseases of the Liver (p 751)

C J WATSON

are recurrent attacks of jaundice and often of paroxysmal pain associated with a palpable cystic tumor and appearing in childhood (McWhorter) The treatment is surgical

DISEASES OF THE PANCREAS

BECAUSE of the many important functions of the pancreas some of which are associated with those of other parts of the alimentary tract diseases of the pancreas were for many years confused with those of the stomach liver and intestinal tract The modern history of the study of the diseases of the pancreas begins with the contribution of Friedreich published in 1857 The knowledge of such phases of the pathology of the pancreas as gangrene fat necrosis hemorrhage acute and chronic inflammation and the relation of the pancreas to diabetes gradually increased during the following three decades Chiari in 1876 described a case of sequestration of a gangrenous pancreas Balser in 1882 was the first to describe accurately fat necrosis as seen in the pancreas and adjacent fatty tissue American pathologists added to the subject when in 1886 Draper described pancreatic hemorrhage as the cause of sudden death and Reginald Fitz in 1889 clearly established the clinical entity of acute pancreatitis In the same year von Mehring and Minkowski published their classic paper on the relationship of diabetes mellitus to the internal secretion of the pancreas

Since that time the elaborate monographs of Oser Opie and Mayo Robson the work of Sweet and the epoch making contribution of Banting in perfecting insulin in the treatment of diabetes have brought the subject to its present position of importance in both medicine and surgery

Pathogenesis —Before classifying the diseases of the pancreas it is essential to point out certain facts in the physiology and pathology of the pancreas The pancreas has both an internal and an external secretion The former has to do with the metabolism of carbohydrates which is apparently the one vital function of the pancreas The external secretion collected by a duct system and emptied as pancreatic juice into the duodenum contains the proferments or zymogens which when activated have to do with the digestion of proteins, fats and carbohydrates The most potent stimulant of the production of pancreatic juice is secretin which is absorbed from the duodenum and carried by the blood to the pancreas The two constituents of the pancreatic juice most important in the study of pancreatic disease are the trypsinogen and steapsinogen These are inactive in the ducts and parenchyma of the organ but when activated are powerful ferments The normal activating agent for trypsinogen which transforms it at body temperature immediately into trypsin is the enterokinase produced by the cells of the mucosa of the small intestine Steapsinogen on reaching the duodenum is normally transformed by some constituent of the bile into the fat splitting ferment steapsin

Infection or trauma may cause activation of the zymogens of the pancreatic juice in the gland itself or in the adjacent tissues and thus gives rise to the characteristic and pathognomonic lesions of protein and fat autodigestion which are seen at operation or autopsy and to the various grades of inflammation described as acute pancreatitis Acute lesions are the result of the action of both these ferments but the distressing and often fatal disturbances which accompany such changes are due to the proteolytic digestion of the blood vessels and living protein of the pancreas and adjacent tissues Thus the action of trypsin is all important in the etiology of these acute lesions From the experimental work of Sweet and others it would seem that, in the acute lesions trypsinogen is transformed into trypsin by an activating substance produced by autolysis of the pancreatic tissue An injury sufficient to produce local necrosis and subsequent autolysis of pancreatic tissue with activation of trypsinogen may result from direct trauma hemorrhage (as in apoplexy of the pancreas) or acute bacterial infection Delezeune first demonstrated the

biliary obstruction as evidenced by less than 5 mg of fecal urobilinogen and 0 3 mg of urinary urobilinogen per day is usually indicative of cancer of the biliary tract This has been referred to in the discussion of calculous jaundice The icteric index is often over 100, while in calculous jaundice it is usually considerably under this level In the various forms of parenchymal jaundice the icteric index varies much more widely The importance of palpating a smooth non tender distended gallbladder may be noted again as favoring carcinomatous biliary obstruction This has also been referred to in the discussion of calculous jaundice

Postoperative *stricture of the common duct* must be distinguished from cancer of the ducts The history of onset of jaundice shortly after cholecystectomy usually serves to indicate the presence of the former condition In many cases the general condition remains relatively good in spite of long continued jaundice quite in contrast with the progressively downhill course of cancer of the bile ducts Traumatic stricture may or may not be associated with complete biliary obstruction, or with suppurative cholangitis Benign stricture of the common bile duct of nontraumatic origin is extremely rare (Walters)

Prognosis—Death usually occurs within a few months from the time of onset of symptoms

Treatment—If the disease is obviously not too far advanced, operation should be carried out In occasional cases it is possible to resect a small primary carcinoma of the common bile duct In one such instance observed by the writer the surgeon was able to remove all of the primary tumor so far as could be determined microscopically it was further possible to anastomose the remaining portions of the duct over a T tube This patient recovered from the operation and was relatively well for a period of eight months but subsequently died of metastases Such cases emphasize the need for early diagnosis and operation In patients where the tumor is inoperable anastomosis of the gallbladder to the stomach or small intestine may prolong life or at least bring relief from otherwise intractable pruritus

The preoperative preparation of these patients, especially the use of vitamin K is the same as already described for stone in the common duct except that duodenal drainage is not employed

CONGENITAL ABNORMALITIES OF THE BILE DUCTS

Congenital Obliteration—This condition is probably due to developmental aplasia The process is confined to the lower portion of the common bile duct in about 16 per cent of cases (Holmes), while in the remainder the ducts within the liver are also obliterated The disease is characterized by deep jaundice coming on shortly after birth and gradually increasing The stools are acholic, and contain not more than traces of urobilinogen The urine contains much bilirubin and no urobilinogen These features permit distinction from icterus neonatorum or erythroblastosis ('kernikterus') The liver is enlarged and usually exhibits obstructive or biliary cirrhosis The spleen may be palpable thus necessitating differentiation from congenital syphilis In addition to the positive Wassermann and other features of congenital syphilis the exclusion of bile from the intestinal tract is not as complete Surgical exploration should be carried out in the hope that the obliterative process is limited to the lower part of the common duct Even where operation has been successful however the result has been but temporary Infection of the biliary tract follows sooner or later upon anastomosis of the gallbladder to the stomach or small bowel

Congenital Cystic Dilatation of the Common Bile Duct—This is a rare condition which is probably related to localized obliteration or stricture of congenital origin In some cases no obstruction has been found The cystic dilatation usually involves the middle and upper parts of the duct The cyst at times attains the size of a full term fetus Clinical features suggesting this condition

Presbyterian Hospital New York City the fulminating hemorrhagic form the suppurative type and abscess of the pancreas were associated with a cholangitis and chronic cholecystitis

Symptoms —In the hemorrhagic and diffuse suppurative types the onset which is sudden is characterized by agonizing and constant pain in the epigastrium or about the umbilicus with severe nausea and vomiting and symptoms of collapse A rapid pulse of low tension and an ashy cyanosis are not uncommon Extreme tenderness over the pancreas extending into the costovertebral angles when the retroperitoneal tissue is involved is characteristic The muscular rigidity is not as marked as in perforated ulcer of the stomach or duodenum In patients with the less fulminating lesions obstipation is common and the most frequent error in diagnosis is confusing it with acute intestinal obstruction

The constant agonizing pain the symptoms of collapse and the paralytic ileus have been explained as the result of stretching of the celiac plexus which is involved in the edematous peripancreatic tissue but the experiments of Sweet point to localized peritonitis and profound toxemia as the cause of the fulminating symptoms

The less severe forms of acute pancreatitis associated with edema of the pancreas and retroperitoneal tissue in the region of the pancreas frequently show symptoms of severe pain radiating to the back with tenderness across the pancreas but these forms as a rule do not produce the profound shock or the rapid pulse and cyanosis seen in some of the more severe forms

Diagnosis —Intestinal obstruction acute peritonitis due to the perforation of an ulcer or diseased appendix and acute cholecystitis are the conditions most frequently confused with acute pancreatitis In any obese individual giving a history of a heavy meal with alcoholic excess or of gallstone attacks or of the recurrent digestive disturbances of chronic cholecystitis acute pancreatitis should be suspected When such histories are given by patients who show extreme or even moderate tenderness over the pancreas there is sufficient evidence for diagnosis

Within the last few years attention has been called to the very important laboratory finding of an elevation of amylase in the patient s blood serum This is caused by a sudden blockage or compression of the duct of Wirsung or of the duct of Santorini as a result of edema or sudden blockage by calculus In some of the cases observed at the Presbyterian Hospital the serum amylase has been found to be as high as 130 units the normal being within the range of 15 to 30 units The finding of an elevated serum amylase in the presence of acute upper abdominal pain with tenderness across the upper abdomen points very emphatically to the diagnosis of acute pancreatitis

Treatment —De Takats has given a very excellent summary of the clinical picture of acute pancreatitis and has made a real contribution to the preoperative diagnosis and treatment He emphasizes the importance of preoperative management of the patient in shock as evidenced by low blood pressure and high red blood cell count with the administration of dextrose and insulin to combat the depletion of liver glycogen and the liver damage seen in these cases Dextrose should be given in a 10 per cent solution with Ringer s up to 100 Gm together with 20 to 30 units of insulin

The former emphasis by surgeons on the importance of immediate operation in all cases of acute pancreatitis is being modified at the present time in many clinics because it is now appreciated as a result of serum amylase studies and delayed operation that many patients recover without surgical therapy from mild attacks of acute pancreatitis particularly those associated with edema of the organ For this reason the author now feels that a more conservative attitude is justified in cases presenting a picture of pancreatitis If while under observation in a hospital the patient shows marked improvement after the above described therapy for shock and blood concentration it is justifiable to observe him for a few more hours noting the improvement in pulse color and signs of peritoneal irritation If later the patient shows a spread of peritonitis he is then in much better condition for operation and it can be done with far greater safety than it could with the patient in profound shock

At the time of operation the prime indication is for drainage of the infected fluid

presence in bacteria of an activating substance similar to enterokinase in its action on trypsinogen In recent years Dragstedt and his associates have produced convincing evidence that certain of the acute pancreatic lesions, commonly associated with bile invasion of the pancreatic ducts are the result of the destructive action of bile salts and that the bacteria in the ducts and pancreatic tissue especially the anaerobes growing in the damaged or necrotic tissue increase the damage and induce the toxic symptoms

Morbid Anatomy—It is evident that the degree of trypsin and steapsin digestion determines the pathologic findings at various stages of acute pancreatitis Lesions vary from an edema of the pancreas and retroperitoneal tissues and peritoneal exudate to extensive hemorrhage into the gland and peripancreatic tissue with necrosis of the gland and more or less fat necrosis in the pancreas and peritoneal fat according to the stage and severity of the disease In these lesions the activating agent of the steapsinogen is apparently independent of the activator in the bile It is the presence of typical areas of fat necrosis—round pearly white spots in the subserosa of the mesentery in the peritoneal fat and in the interlobular fat of the pancreas—that is always indicative of pancreatic disease The absence of such fat necrosis does not however rule out the possibility of acute pancreatitis Fat necrosis a dirty sanguineous exudate in the peritoneum, and edema induration, and enlargement of the pancreas are the most common abnormalities found at operation Usually all three and always at least two of these changes are seen during acute pancreatitis

If autolysis of the gland causes progressive hemorrhage necrosis and gangrene of more or less of the pancreas results Infection may be followed by varying degrees of edema and suppuration and by the formation of abscesses

Symptoms—In the severe types of pancreatic disease associated with necrosis and autolysis of the pancreas and hemorrhage into the gland there is an acute and fulminating toxemia often sufficiently severe to cause death within a few hours To Sweet belongs the credit of focusing the attention of the profession in this country on this dreadful intoxication—the *Pancreasvergiftung* of the Germans As a result of his experiments, corroborated by many investigators he has demonstrated that when the sterile excised pancreas of one animal is placed in the peritoneal cavity of another animal of the same or a different species the animal into which the pancreas is transplanted invariably dies with symptoms of profound toxemia Immediate autopsy reveals evidence of fat necrosis an irritative peritonitis most marked about the transplanted pancreas which is softened and disintegrating and a dirty peritoneal exudate The animal s own pancreas is not pathologically changed Sweet maintains and very logically that the pancreatic juice of the transplanted organ is the cause not only of autolysis of the host's tissue but also of the profound intoxication Whether this poison be elaborated by the destruction of the animal s own pancreas or within the transplanted pancreas the effects are the same

It is the quantity of this poison which determines the severity of the constitutional symptoms of acute pancreatitis and explains why in some cases the constitutional symptoms are so overwhelming when the anatomical changes are so slight

ALLEN O WHIPPLE

ACUTE PANCREATITIS

Definition—*The term* 'acute pancreatitis" includes the hemorrhagic suppurative and gangrenous types

Occurrence—The disease appears to be most common in adult males who eat and drink heavily The fact that in many patients the onset occurs one or two hours after a heavy meal is explained by recalling that the pancreas is most active at that time and that any injury, such as a small hemorrhage or distention *of a duct* favors the action of trypsin and autolysis The disease is frequently associated with cholecystitis and cholelithiasis A calculus lodged in the papilla of Vater may dam up the bile until it is forced back into the pancreatic duct Cases reported by Opie and subsequently by many other observers have clearly demonstrated this In a series of patients at the

There are a certain number of cases that even at operation cannot be differentiated from carcinoma of the head of the pancreas For these cholecystogastrostomy or chole cystoduodenostomy is necessary Permanent relief and disappearance of jaundice are the therapeutic diagnostic tests

ALLEN O WHIPPLE

PANCREATIC CALCULUS

Pancreatic calculi are rare and are usu ally found accidentally at autopsy Their presence is practically never recognized dur ing life They are usually small are com posed of calcium phosphate and calcium carbonate and in most cases are situated in the main pancreatic duct They are usually associated with chronic pancreatitis

ALLEN O WHIPPLE

TUMORS OF THE PANCREAS

Gulecke s classification of pancreatic cysts is the most comprehensive He divides them into

Adenocystomata or cystic new growths which are multilocular as a rule and most often found in the tail of the pancreas

Rentention cysts the most common form which develop when the ducts are ob- structed and are usually associated with a chronic pancreatitis

Degeneration cysts which result from a softening and cystic degeneration of pan creatic tissue caused by necrosis or hemor rhage

Pseudocysts which are characteristically located outside the parenchyma of the pan creas and as a rule occupy the lesser sac These frequently form after injury to the pancreas and contain, at first changed blood later a clear glairy fluid composed largely of pancreatic juice

Symptoms and Diagnosis—Since Gussen bauer first diagnosed the condition in 1882 the symptomatology has been carefully studied but even today it is not clear cut Pain in the epigastrium or in the left upper quadrant the development of a palpable tumor in the region of the epigastrium or umbilicus and symptoms of indigestion simi lar to those of chronic pancreatitis are the common manifestations Because of the po sition of such cysts above the stomach or between the stomach and colon gastric and colonic inflation with air may aid diagnosis The x ray examination of the abdomen which has been inflated with a few hundred cubic centimeters of oxygen or sterile air may demonstrate the cyst A steadily en larging mass in the upper abdomen is the most characteristic sign

Treatment—Aspiration is a bad practice An exploratory incision under novocain an esthesia is desirable both to establish the diagnosis suggested by the other evidence and to evacuate the contents if the enlarge ment proves to be a cyst Suture of the open ing of the cyst to the abdominal incision (so called marsupialization) is then ad visable in order to prevent accumulation of fluid within the cyst

The use of sclerosing solutions such as sodium salicylate and quinine urea or even weak solutions of potassium hydrate may prove of great help in closure of the fistulae resulting from marsupialization of pancreatic cysts

Benign Tumors—*Adenoma of the Islet Tissue of the Pancreas Excision for Hyper insulinism*—The purpose of the operation is to remove single or multiple adenomas in tact with the least damage to the normal pancreatic tissue

After the diagnosis of chronic hypo glycemia is established and hepatic and pitu itary causes have been ruled out the patient should have a course of medical therapy of three to four weeks to determine the response of the individual to conservative measures If it is found that the blood sugar values are continuing to remain low and that seizures are controlled only on a high carbohydrate intake an exploratory celio tomy is indicated

CASE SELECTION—Patients in whom the diagnosis of hyperinsulinism is definitely made by excluding pituitary adrenal and hepatic etiology who have failed to re spond to medical therapy over a period of several weeks who continue to show low fasting blood sugar values and are becom ing obese because of the large amounts of sugar and carbohydrate required to control their hyperinsulinism should be operated upon

and of the released pancreatic ferments with the least trauma to the pancreatic tissue Some surgeons advise the breaking through of the capsule of the pancreas along its lower margin in order to provide for a release of tension If this can be done under vision it probably is wise to do so but in the major ity of cases the tissue is so edematous that *it is difficult to obtain a clear view of the* pancreas Therefore celiotomy with drain age of the involved portion of the pancreas and decompression of the bile ducts if jaun dice is present is the procedure of choice Modern methods of transfusion if followed by saline drip infusion can be carried on if necessary during and after the operation

Allen O Whipple

CHRONIC PANCREATITIS

The pathologic change characteristic of chronic pancreatitis is an increase in the interstitial connective tissue which replaces more or less of the parenchyma of the gland Opie has pointed out two histologic types of chronic inflammation (1) the interlobular usually associated with lymphangitis in which the increase of fibrous tissue is limited to the tissue between the lobes and (2) the interacinar in which the new growth of con nective tissue invades the interacinar spaces replacing the parenchyma and involving the islands of Langerhans In the interlobular variety, the lesion is more apt to be limited to a part of the pancreas especially to the head where it is most commonly associated with a descending infection of the biliary tract The interacinar type usually involves the entire gland and is frequently associated with diabetes mellitus

The increase in connective tissue may be caused by an arteriosclerotic or endarteritic condition of the vessels by a syphilitic proc ess or by blocking of the ducts Most often it is the result of long standing and per sistent infection of the lymphatics of the pancreas which communicate freely with those of the biliary tract duodenum and transverse colon

Symptoms and Diagnosis—Epigastric distress bloating and belching epigastric tenderness constipation or diarrhea and irregular jaundice are symptoms *common to* chronic pancreatitis They may also occur with lesions of the biliary system If how ever in addition the patient suffers from a sense of fulness and the stools are large foul and fatty, and contain undigested meat fibers or if there is sugar in the urine a diagnosis of chronic pancreatitis is probably correct The decrease or absence of pancre*atic ferments in the duodenal fluid* is added evidence The fluid should be obtained by the Einhorn tube and examined imme diately

Carcinoma of the pancreas is most dif ficult to differentiate from chronic pancrea titis Irregular jaundice a history of biliary colic and absence of an enlargement of the gallbladder suggest chronic pancreatitis while jaundice of gradual onset steadily in creasing without a history of biliary colic, and a palpable pear shaped gallbladder point to carcinoma of the head of the pan creas, or carcinoma of the papilla of Vater The newer technic of gastro intestinal fluoro scopy makes it possible to differentiate be tween *gastric carcinoma* and the chronic pancreatitis in spite of the similarity of symptoms The use of the duodenal tube to obtain duodenal *juice for* determination of pancreatic ferments may be of value in differentiating a carcinoma of the ducts from chronic pancreatitis and carcinoma of the pancreas

Treatment—For the interacinar type associated with glycosuria the usual medical measures employed in diabetes may be used Because of the digestive disturbances fats and proteins have to be largely eliminated from the diet Pancreatic extract is of real benefit in some cases, and may be given in doses of 0 3 to 0 6 Gm in salol coated capsules after *meals*

For the common interlobular type of pan creatitis the same treatment should be tried but surgery should be *employed to* remove any focus of infection such as chronic chole cystitis or biliary infection In many cases carefully watched at the Presbyterian Hos pital removal of the infected *gallbladder* or drainage of an infected common duct has resulted in permanent recovery from the symptoms referable to the diseased pan creas The results at the Mayo Foundation and at Lankenau clinic have for many years *proved the efficacy* of surgery in this disease

the lower end of the common duct can best be accomplished in early favorable cases in a one stage procedure The radical operation for these tumors of the ampullary region and pancreas based on the principle of wide *en bloc* removal of the tumors as required in modern cancer surgery, is evidently in an evolutionary stage Many more cases with five year survivals will be required before valid claims can be made for the operations as done at present But it must be remembered that these patients untreated have an average of six months survival from onset of symptoms until death Many of them are tortured with the uncontrollable itching of obstructive jaundice The considerable risk of 30 to 35 per cent is justified if they can be made comfortable even for a year or two If only these patients could be referred to the surgeon before they are studied to death while the cancer is small and localized and before the patients are seriously ill with weeks of obstructive jaundice a far lower operative mortality and a much longer survival would result

DISEASES OF THE PERITONEUM

General Considerations —The peritoneum is the serous membrane which lines the walls of the abdominal cavity and is reflected to envelop the structures within the peritoneal cavity The portion of peritoneum which lines the walls of the abdominal cavity is called the parietal peritoneum and that which covers the viscera the visceral peritoneum In the male the peritoneal cavity is a closed sac but in the female the open ends of the fallopian tubes render peritoneal infection by that route possible

The reflections from the parietal peritoneum to the viscera are composed of two layers which form the mesentery omentum and peritoneal ligaments The peritoneum is composed of a layer of endothelium resting on a thin layer of connective tissue In the development of the embryo and rotation of the intestine the relations of the peritoneum become exceedingly complicated in that various compartments are formed all of which under normal conditions are in communication with one another but which in inflammatory processes may become separate compartments The two main compartments are the greater and the lesser and they are connected by the foramen of Winslow The main divisions of the greater sac are the right and left lumbar the central the pelvic and the subphrenic

In addition to surrounding and separating the viscera from one another and suspending them by various ligaments the peritoneum serves as a medium through which the blood lymph and nerve supply to these structures is carried The smoothness of the peritoneal surface and the fact that there is normally a small amount of fluid in the peritoneal cavity permit the movements of the viscera to take place with the greatest freedom

The defense mechanism of the peritoneum and the great absorptive power of this structure are in large part attributable to its enormous area which is approximately equal to that of the surface of the body The omentum is a large factor in protection against infection Its extent its close contact with the contents of the abdominal cavity its rich blood supply and its mobility give it the capacity to seal off localized infections or to become adherent to the parietal peritoneum and wall off large portions of the abdominal cavity The entire peritoneum possesses tremendous power of absorption and it has been shown that the rate and degree of absorption are the

END RESULTS —The author has operated on seven cases of hyperinsulinism six with excision of one or more adenomas of islet tissue as proved by pathologic examination the seventh with excision of four fifths of the pancreas These have all been followed for periods of one to three years All were cured of their hypoglycemia and 'insulin shock seizures One patient who had two adenomas and remained cured of his hyperinsulinism for twenty eight months was admitted to another hospital as an emergency and died of hemorrhage from a bleeding duodenal ulcer which developed a year after his operation for removal of islet tumors (For a review of all reported cases of hyperinsulinism up to 1938 see the article by Whipple in International Journal of Surgery 1938)

Benign cystadenoma of the pancreas is relatively rare and is often exceedingly difficult to differentiate from a retention cyst of the pancreas The relative amount of adenoma and cyst formation determines the pathologic findings

Malignant Tumors —Tumors of the pancreas are usually malignant and almost always carcinomatous Adenocarcinoma is the most frequent type Carcinoma usually occurs in the head of the organ and rapidly involves the common bile duct and adjacent lymph nodes

Symptoms —The symptoms vary with the location of the tumor but great weakness loss of weight and extreme anorexia are always present

If the tumor is in the head jaundice appears, as a rule gradually Unless the gall bladder has been previously inflamed it enlarges to an easily palpable pear shaped mass as the jaundice deepens There may be glycosuria but it is rare The presence of a palpable mass in the region of the pancreas is also very infrequent The pain and tenderness vary with the amount of involvement of the celiac plexus The pain is characteristically of a severe boring or grinding type and extends through to the back During the jaundice the stools are foul clay colored and fatty The blood clotting and bleeding times are prolonged as the jaundice deepens or persists

Diagnosis —As has already been stated differentiation between these tumors carcinoma of the papilla of Vater or carcinoma of the common duct and chronic pancreatitis, is almost impossible A persistent deepening jaundice coming on gradually without pain, in an elderly individual with a palpable gallbladder is almost certainly a sign of carcinoma of the head of the pancreas The use of the duodenal tube for a study of pancreatic ferments may help in the differential diagnosis of carcinoma of the common duct above the papilla and the other lesions

Treatment —In the late stages no treatment gives relief In the early stages the patient may be spared several weeks of great emaciation and pruritus by anastomosis between the gallbladder and stomach or duodenum In five patients seen by the writer a diagnosis of carcinoma of the head of the pancreas was made during operation all were relieved of symptoms for twelve to thirty six months by a cholecystenterostomy Cases that eventually prove to be chronic pancreatitis illustrate the difficulty of the differential diagnosis and the advantage of applying surgery to an otherwise incurable condition

Within the last few years progress has been made in the therapy of carcinoma of the papilla of Vater and early carcinoma of the head of the pancreas In 1938 the writer (Amer Jr of Surgery April 1938) published a new method of dealing with these lesions The operation is carried out in two stages in the first stage we ligate the common duct below the cystic duct and do an antecolic cholecystojejunostomy on the Roux principle of anastomosing the distal cut end of the jejunum to the fundus of the gallbladder with an end to side anastomosis of the proximal cut end of the jejunum to the side of the jejunum 10 to 12 cm below the cholecystojejunostomy

After three weeks the second stage should be done with first a gastrojejunostomy followed by an excision of the descending or second portion of the duodenum the ampulla of Vater with the lower end of the common duct and a wedge shaped portion of the head of the pancreas with ligation of the cut end of the pancreatic duct and closure of the pancreatic stump

More recently we have found that the radical removal of carcinoma of the head of the pancreas of the ampulla of Vater or of

While peritonitis due to colon bacilli is less fatal and fulminating than the other forms it is unfortunately usually a mixed infection and the other organisms frequently streptococci although not the primary invaders increase the seriousness of the infection to a marked degree

The streptococcus probably invades the peritoneum as frequently as the colon bacillus being introduced in the same manner as just mentioned although the most frequent sources are puerperal sepsis and 'infection introduced from without The exudate in such cases is thin watery slightly purulent odorless and contains no flakes of fibrin Peritonitis of this type is perhaps the most fatal and fulminating of all

The gonococcus may invade the peritoneum in the course of gonorrhea This is more common in females but may also occur in males Peritonitis in such cases is usually confined to the pelvis although on occasions it may be generalized The exudate is plastic and rapidly produces dense adhesions

The pneumococcus may be found in mixed infections but is also found in pure culture Pneumococcal peritonitis is usually observed in children between the ages of three and seven years although it has been known to affect adults also The condition in males is primary but in females secondary The pneumococcus in these cases invades the peritoneal cavity by way of the genital tract through the fallopian tubes and infection begins as pelvic peritonitis The exudate at first is thin watery and contains no flakes of fibrin within a few days however it becomes thick purulent and contains much fibrin This tends to cause adhesions and to localize the infection

Incidence—Little has been written on the relative frequency of acute peritonitis Some interesting figures were recently obtained by Pflaum however in the review of a series of 14 263 consecutive necropsies at the various hospitals in Minneapolis and St Paul from 1920 to 1932 There were 1000 cases (7 per cent) of general peritonitis in this group

The condition was considerably more frequent in females than in males and the greatest number of patients had been between the ages of twenty and thirty years The incidence in females reached its peak during this decade because the peak of gynecologic diseases occurs in this period Peritonitis was more frequent in males between the ages of forty and seventy years and perforated peptic ulcer and carcinoma were found to be the important causative factors The bacteriology was in accord with what has already been given

Peritonitis developed as a postoperative complication in 22 1 per cent of these cases and was attributed to appendicitis in 12 6 per cent to tuberculous infection in 10 per cent to abortion in 7 7 per cent to malignant tumor in 6 4 per cent and to perforating peptic ulcer in 4 8 per cent The lesions were also studied from the standpoint of mode of origin and 522 were found to have arisen from the alimentary tract 193 from the female reproductive organs and 88 from hematogenous infections The remainder were about equally distributed with respect to the source of infection

Morbid Anatomy.—The pathologic changes which occur in acute peritonitis are dependent on a large number of factors so that the course of peritonitis from a pathologic standpoint is by no means constant In massive infections resulting from rupture of a viscus or an abscess there is a prompt and general reaction which exhibits the characteristic changes seen in inflammation of any serous membrane The resistance of the peritoneum to certain types of infection is well known and certain types of organisms injected into the peritoneum of animals will produce little reaction The usual immediate changes which occur in the peritoneum are an increase of blood in the involved region and a gradual change from the normal glistening to a glazed appearance and exudation of plastic lymph of varying amount according to the nature and the extent of the infection The amount of fibrin which is formed also depends on the nature of the infection

In general the less serious the type of organism the greater the amount of fibrin and the greater the extent of the agglutination of the intestines the better the prognosis For instance in streptococcal peritonitis the amount of fibrin is small so there is little evidence of protective covering present A large quantity of thick pus within the abdo

same in all portions of the peritoneal cavity Some authors contend that absorption is more rapid from the diaphragmatic area than from the pelvic area, thus the basis for Fowler s position, but this contention is probably attributable to the fact that the lymphatics of the diaphragm are more easily *demonstrated than other peritoneal lymphatics* There is some controversy as to whether the lymphatics or the blood vessels are the main route of absorption There is no doubt that this process takes place through both, but the evidence suggests that the absorption from the blood vessels is greater

Much of the confusion in the classification of peritonitis results from an attempt to identify the different types according to the source of the infection (for example exo genous or endogenous) to its extent (for example local or general) to the course which it is pursuing (for example spreading or localizing) to the situation of the peritonitis (for example pelvic or central) or to the bacteria which are present (for example, *streptococci staphylococci, colon* bacilli or pneumococci) For practical pur poses, division of peritonitis into the acute and chronic forms is as satisfactory as any

DONALD C BALFOUR

ACUTE PERITONITIS

Etiology—Acute peritonitis may be at tributed to many causes and only the more important are listed here These may be divided into certain general groups of which the most common are

Infective Lesions—These may be situated in the appendix the pelvic organs of females the gallbladder or in diverticula of the colon they may be associated with acute diseases of the pancreas Rupture of an abscess or of pocketed secretions also gives rise to infec tive lesions

Noninfective Lesions—Aseptic peritonitis or noninfected inflammation of the perito neum occasionally is produced by mechan ical injury by irritation caused by antisep tics or by extravasation of blood urine bile pancreatic juice or the contents of cysts The diagnosis of aseptic peritonitis how ever, is never justified without surgical ex ploration

Acute Perforation of Lesions of the Gastro intestinal Tract—These lesions include chronic or acute ulcer, particularly of the stomach and duodenum, but also any ulcera tive process, benign or malignant, of the gastro intestinal tract for example typhoid ulcer, tuberculous ulcer and the lesions of chronic ulcerative colitis

Intestinal Obstruction—The intestinal obstruction may be either mechanical or paralytic Strangulated hernia paralytic ileus, intussusception volvulus mesenteric throm bosis malignancies and the like are frequent causes The rupture of intra abdomi nal organs by direct or indirect trauma either from crushing or penetrating injuries may produce peritonitis Peritonitis rarely results from rupture of solid organs except when extravasated blood becomes infected

Primary Peritonitis—This is compara tively rare usually fatal and most often seen in children

Postoperative Peritonitis—Peritonitis may occur after any intra abdominal pro cedure but it more frequently occurs fol lowing operations that involve opening of that part of the intestine in which the con tents are highly virulent as in the colon Peritonitis may also be caused by organisms introduced from without by faulty technic, by direct contamination from infective ma terial from the nose or throat of operating room personnel from soiling during the op eration from subsequent leakage from a suture line in the gastro intestinal tract or from rupture of a circumscribed accumula tion of infective material

Bacteriology—Although it is not possible to make a satisfactory classification of per itonitis on the basis of the causative bac teria it seems important to mention the organisms most frequently found in the per itoneal exudate These in order of frequency are *Bacillus coli* streptococcus staphylo coccus pneumococcus gonococcus *Bacillus pyocyaneus Clostridium welchii* and other anaerobes

Colon bacilli are usually introduced by rupture of an acute appendix or by per foration or rupture of some portion of the bowel The exudate is profuse purulent, flaked with fibrin and may have a fecal odor

Pain—The pain of peritonitis has no particular characteristics except that it is at first extremely severe when widespread contamination of the peritoneal cavity has taken place, such as occurs in perforated ulcer The pain is so acute in these cases that the patient gives every evidence of profound shock and of impending death He makes every effort to avoid moving and lies in bed in a position which will put the least strain on the abdominal muscles Shallow thoracic respirations limit movement within the abdomen as much as possible In the majority of cases pain remains localized as long as does the peritonitis One of the most deceptive features particularly that associated with an acute appendicitis is that there may be a quiescent period between that stage of infection and the beginning of a general peritonitis which may deceive the attending physician as to the true condition of affairs The mode of onset of the pain in peritonitis is not constant It begins suddenly when the abdominal infection is widespread but in many cases the process extends so slowly that at no time is there severe pain

Vomiting—Vomiting almost always occurs in some stage of general peritonitis It is characteristically of the nature of a regurgitation and as the process continues the vomitus is more and more like that of the secretions of the upper gastro intestinal tract although it has a fecal odor there are seldom any fecal particles visible This vomiting is evidence of more or less complete paralysis of the intestinal tract and it is a very ominous sign The vomitus is usually of small amount and is regurgitated frequently and without effort

In the early stage of peritonitis peristalsis is normal and hyperactive but as the process extends gradual paralysis of the intestinal tract takes place and in the later stages peristalsis is completely absent Other symptoms such as jaundice and increasing shock are evidences of the profound toxemia The blood picture usually reveals leukocytosis the cell count varying between 10 000 and 30 000 per cu mm One should be suspicious of the presence of some other lesion particularly pneumonia in those cases in which there is an extreme elevation Occasionally there may be but little change in the leukocyte count but a shift to the left in the Schilling count is present in these instances In general the leukocytosis is indicative of the degree of infection so that in the chronic forms of peritonitis for example, there may even be a leukopenia The urine contains albumin and casts as evidence of the toxemia present Blood cultures are usually negative

While this is a brief picture of a typical case of peritonitis there are many atypical cases The reverse of the picture is occasionally seen, chiefly in elderly people, in which there may be no symptoms at necropsy however a diffuse peritonitis may be found There may have been no pain whatever no distention no elevation of temperature and even no elevation in pulse rate until a few hours before death These atypical cases are usually encountered in patients who are markedly debilitated from some other disease particularly cancer and probably because of the low resistance, or the type of infection little reaction to the infection occurs

Between these two extremes the absence of certain symptoms may make the diagnosis of peritonitis difficult and even impossible until more definite signs develop Because of this and because the great majority of cases of fatal peritonitis are secondary to conditions which can be corrected by timely surgical intervention correct diagnosis of the primary condition is of paramount importance rather than any attempt to evaluate signs and symptoms which may be evidence of peritoneal involvement Acute appendicitis and perforated ulcer are the most important examples of this It is also true in cases in which direct or indirect trauma has given rise to evidence of some intra abdominal injury If there is delay until definite evidences of peritonitis are present it is usually too late to save the life of the patient whereas careful consideration of the significance of the signs and symptoms present in respect to the type of injury will force a decision as to whether or not an abdominal exploration is indicated in order to determine the extent and nature of the injuries

Differential Diagnosis—The more important conditions from which peritonitis must be distinguished are (1) pneumonia

men, such as is seen in infections by staphylococci or colon bacilli, is of much less serious import than a small quantity of thin serous fluid as is present in streptococcal infection

Except in the primary type of peritonitis the infection usually begins locally and if it does not extend beyond a certain area the inflammatory process subsides and the area of involvement is soon restored to normal The rapidity and completeness with which this local peritionitis resolves are remarkable If however the infection spreads and involves the general peritoneal cavity, it will in the majority of cases prove fatal the exceptions being those in which the bacteria or their toxins are not of the virulent type In those cases of general peritonitis in which recovery has occurred the capacity to absorb the products of the inflammation is evidenced by the fact that their complete disappearance may take place This capacity however, varies in different individuals and in some the ability to produce fibrin is so marked that adhesions of the widest extent and firmness remain The fluid exudate which always accompanies peritonitis of any extent tends to accumulate to a greater or lesser degree in the more dependent portions of the abdominal cavity namely the pelvis right and left flank and subphrenic region If the patient recovers a localized abscess may remain in one of these regions

The major intra abdominal findings at necropsy in cases of general peritonitis are the distention or matting together of intestinal coils and the peritoneal exudate This exudate varies in consistency color and amount depending on the amount of fibrin the types of organisms present and the source of the infection It may be hemorrhagic as in perforating wounds or malignant disease In some cases the infection may be so virulent as to cause death within twenty four or forty eight hours Under these circumstances little or no exudate may be present

Symptoms—The symptoms of acute peritonitis vary *considerably* both in character and degree and they are in a general way dependent on the extent and nature of the infection and the *resistance of the patient* Local peritonitis is a condition very commonly associated with inflammatory processes in the abdomen While the process remains *local* the symptoms if any are present, are indistinguishable even though they are not a constituent of this local process There may, however be local signs of such a peritonitis particularly in regional rigidity of the abdominal musculature It is when peritonitis becomes more general as it does in cases in which it is a blood borne infection and, therefore of the primary type, that its typical symptoms are displayed The cardinal symptoms in such cases are always present and the clinical picture of a patient with general peritonitis is when once seen never forgotten

Pain and vomiting are early symptoms Irritability of the intestinal tract may first be evidenced by hyperperistalsis later on by intestinal paresis Anxiety is a characteristic sign and the patient's appearance in the later stages was so vividly described by Hippocrates that the term Hippocratic facies is applied A sharp nose hollow eyes collapsed temples, the ears cold contracted and their lobes turned out the skin about the forehead being rough distended and parched the color of the whole facies being brown black livid or lead colored" The position in bed with the thighs flexed and the shallow thoracic respirations are also striking features Hiccups may be an early symptom The patient's mental alertness even to within a short time before death is almost pathognomonic Both the pulse rate and temperature are elevated although in some cases the latter shows very little elevation in the early stages, a continued rise in pulse rate and a falling blood pressure and cyanosis however are ominous signs. Sooner or later there are evidences of dehydration in the dry tongue and of extreme thirst Abdominal distention is usual and local abdominal tenderness is frequent muscular rigidity, particularly in the early stages of a fulminating peritonitis is in itself almost sufficient to make the diagnosis In cases in which peritonitis is due to perforation of a hollow viscus with resultant escape of fluid and air into the abdominal cavity the signs of free fluid and air may be elicited on examination The symptoms therefore of general peritonitis are such as rarely leave doubt as to the diagnosis

It is only when there are no signs of improvement or when there is increasing evidence of sepsis particularly in the development of chills a high temperature and leukocytosis that suspicion is aroused of a residual abscess When this abscess becomes of sufficient size a diagnosis can usually be made regardless of its situation Subphrenic accumulations are most important to recognize and in such cases the history is of great value since they usually occur after operations for appendicitis with localized abscess Roentgenologic examination and exploratory needling will usually determine whether or not an accumulation is present in this region

Treatment —Even more important than the early diagnosis and treatment of peritonitis is its *prophylaxis* This consists in the main of recognizing and caring adequately for lesions which if untreated often lead to peritonitis—lesions such as appendicitis pelvic infections of women especially those of gonococcic origin peptic ulcer intestinal obstruction cholecystitis and carcinoma The insurance of absolute surgical and obstetric asepsis is most important Campaigns against venereal diseases and the institution of centers of treatment are essential to the prevention of gonococcic peritonitis Avoidance of purgatives in the presence of abdominal pain is one of the chief prophylactic factors in peritonitis Preoperative treatment consists chiefly of rest starvation the withholding of narcotics and the avoidance of purgatives until a diagnosis has been made

At *operation* much can be accomplished in the prevention of peritonitis besides the removal of the focus responsible for the infection If there is any possibility of peritoneal soiling as in operations on the gastrointestinal tract the application of one of the sulfonamide compounds directly to the region of possible soiling often means the difference between peritonitis and an uneventful convalescence Both *sulfanilamide* 6 Gm (90 grains) and *sulfathiazole* 6 Gm (90 grains) have been used with good results The latter is felt by many to be superior because it is absorbed by the peritoneum less rapidly and therefore produces a high concentration of the drug locally for a longer time it also calls forth a more rapid and prolonged nonspecific peritoneal response of mononuclear phagocytes to deal with any organisms present Throckmorton has shown that sulfapyridine is irritating to the peritoneum and remains agglutinated thus calling forth a foreign body giant cell reaction which results in the formation of adhesions For these reasons it is less desirable for use locally on the peritoneum

Once peritonitis becomes established operation should be begun as soon as possible if the patient is in condition to stand a surgical procedure Of first importance is the removal of the focus (appendix ruptured peptic ulcer etc) which is responsible for the peritonitis Application of one of the sulfonamides (preferably sulfathiazole) to the region of contamination has proved very beneficial in many cases this has been supplemented by the administration of *sulfanilamide subcutaneously* (0 8 per cent solution) the initial dose for an adult is usually 400 to 500 cc subsequent doses are regulated by the concentration of the drug in the blood as a rule it is best to maintain a concentration of 5 to 8 mg per 100 cc *Supportive measures* are helpful As a rule nothing is given by mouth until the patient passes gas by rectum *Fluid balance* is maintained by intravenous administration of a 5 per cent solution of dextrose in distilled water and by the subcutaneous administration of physiologic solution of sodium chloride *Rest* in bed in the semisitting position is employed *Pain* is alleviated by repeated small doses of morphine *Transfusions* of blood or plasma are helpful especially if the patient is anemic or if the concentration of serum protein is low Distention is combated by gastric lavage or in more persistent cases by the indwelling nasal tube either the duodenal tube as advocated by Wangensteen or more recently the double lumen tube (Miller Abbott) which is connected to a constant source of suction The use of a rectal tube with glycerin suppositories enemas and the application of hot stupes to the abdomen may also help relieve the distention Pitressin eserine sulfate and acetylcholine are helpful in combating intestinal paralysis

DONALD C BALFOUR

and pleurisy, particularly in children, which must be distinguished from primary peritonitis, this is usually possible by careful examination if only one condition is present, (2) renal colic which is associated with spasm and rigidity of the abdominal muscles and evidences of shock, (3) intestinal obstruction, which is occasionally difficult to distinguish from peritonitis since they are so frequently associated that it is not always possible to determine which condition is primary, and (4) gallstone colic, in certain types of which there may be an associated rigidity of the abdominal muscles In all conditions in which there is muscular rigidity, this usually disappears or diminishes when morphine is given the rigidity associated with peritonitis on the other hand does not Various other intestinal conditions, such as intussusception volvulus or mesenteric thrombosis may in some cases be difficult to differentiate, although a carefully taken history will usually exclude them In addition any condition that may give rise to any of the symptoms which are present in peritoneal irritations may be confused with peritonitis for example ovarian cyst with twisted pedicle acute pancreatitis lead colic ruptured ectopic pregnancy coronary disease and the gastric crises of tabes

The most important occasions on which peritonitis can be recognized are when it is possible to save the life of the patient by dealing directly with the cause of the peritonitis The most common example of this is in perforated gastric or duodenal ulcer It is fortunate that in this disease the initial symptoms are so severe and so characteristic that it is relatively easy to recognize the condition and if the patient is operated on within a reasonable length of time after perforation recovery is almost the general rule

Prognosis.—The mortality of peritonitis is difficult to establish but it is certain that general peritonitis has by far the highest mortality of any acute intra abdominal disease If peritonitis is localized and remains so recovery is to be expected although a residual abscess is always possible Recovery when peritonitis has extended beyond the localized area is dependent on the virulence of the infection, the resistance of the patient and the power to localize the process The high mortality in peritonitis other than in exceptional cases is due therefore to the toxemia which results from absorption throughout such a large area and the little that can be done to prevent the process from spreading

The actual cause of death in peritonitis is usually considered to be bacterial toxemia resulting from direct absorption from the peritoneal cavity It seems probable however that there would be more recoveries from general peritonitis, and treatment would be more effective in dealing with toxemia if the condition were not so often associated with complications in themselves serious Chief of these complications are intestinal obstruction and pneumonia The frequency with which a pneumonic process of some degree is found in patients who have died of general peritonitis is very high and this is particularly true when peritonitis develops in debilitated patients Similarly the intestinal paresis almost constantly accompanying general peritonitis adds to the picture of intestinal obstruction If it were possible to eliminate this factor it would increase the possibility of recovery The power of the peritoneum and particularly of the omentum to wall off peritoneal infection is so remarkable that if no complicating factors were present recoveries would be more often seen than they are at present

Sequelae.—A special effort should be made to recognize the sequelae of peritonitis, whether local or general as they may be rather easily overlooked The most important of them in as far as intra abdominal conditions are concerned are residual abscesses and of these the most serious are those in the iliac fossa in the pelvis and in the subphrenic region These abscesses follow a varied course and may be gradually absorbed without any significant residua but more frequently unless drainage is instituted they rupture into adjacent structures particularly into the intestinal tract itself or into the general peritoneal cavity or through the abdominal wall

The general symptoms of a residual abscess may be entirely unobserved In the early stages the patient may have been very ill and possibly may have had a continuous high temperature and leukocytosis but no physical signs of an accumulation of pus

terminal picture of intra abdominal malig nant disease The chief diagnostic sign of carcinomatous peritonitis is the presence of blood in the exudate

The symptoms of chronic peritonitis are indefinite They depend to a large degree on the amount of ascites present and of in testinal disturbance by the adhesions In the majority of instances adhesions will exist without symptoms but they may give rise to obstructive symptoms or to some reflex disturbance There may be a recurrent colicky type of pain associated with nausea and vomiting Malaise slight fever consti pation and even a chronic intestinal ob struction might be present There may be ascites or palpable masses present

The treatment hould be surgical when there is a possibility of removing the causa tive factor Laparotomy should not be performed for adhesions unless there are symptoms of obstruction or some marked disturbance of function Much has been at tempted in the prophylaxis of postoperative adhesions This has consisted chiefly in the introduction of a foreign substance into the peritoneal cavity at the time of operation These foreign substances have consisted of various solutions such as amniotic fluid gases such as oxygen and nitrogen, oils and waxes such as olive oil and paraffin and membranes such as the amniotic membrane The results obtained have not been uni formly favorable The Elliott heat treatment of pelvic peritonitis in women has proved *beneficial*

Other than this treatment is sympto matic If enough ascites is present para cente is should be performed the diet regu lated and the patient instructed in the proper use of laxatives and enemas Relief of symptoms may be obtained in many instances by the institution of the simpler procedures the treatment of chronic perito nitis by any radical procedure is to be dis couraged

DONALD C BALFOUR

MALFORMATIONS AND TUMORS

Many malformations of the peritoneum have been observed but rarely are they of clinical significance Rotation of the gut may be interrupted at any phase in its evolution thus giving rise to various peritoneal *bands folds fossae* or *recesses* Lane s kinks an adhesive band stretching between the termi nal portion of ileum and the pelvic perito-neum and Jackson s membrane a peritoneal membrane spreading from the parietal per itoneum to the ascending colon are fre-quently mentioned In rare instances an *absence of the omentum* has been noted A bifid omentum and a third omentum have been reported The abnormal development of the fossae has led to the formation of *intraperitoneal hernia*

Tumors of the peritoneum can be divided into primary and secondary tumors The *en-dothelioma* is the most distinct tumor that originates in the peritoneal structure itself Its rarity justifies omission of further com ment

Secondary involvement of the peritoneum by growths developing in one of the adjacent viscera is frequent Metastatic lesions from carcinoma of any organ in the abdomen or elsewhere are not infrequent in the perito-neum They may occur by direct extension or result from dissemination or transmission through the blood stream

Pseudomyxoma peritonaei is one of the more interesting tumors which usually oc-curs by dissemination It is secondary to rupture of a pseudomucinous cyst of the ovary or of a mucous cyst of the appendix It is characterized by the formation of large gelatinous masses which are more or less *encapsulated and may penetrate any part of* the peritoneal cavity A very similar condi tion can be produced by colloid carcinoma anywhere in the digestive tract Surgical removal of this gelatinous material and the original growth have in some cases given a number of years of comfort Recurrence however is probable and the prognosis is bad

Lipomas fibromas and *sarcomas* (lipomas being by far the most frequent) are occa sionally found in the mesentery and omen tum They arise from the tissue between the peritoneal leaves and are usually connective tissue types of growth *Cysts* of the mesen tery and omentum are seen more frequently These are classified by Ewing as chylous cysts enteric cysts dermoid cysts and intra peritoneal cysts of nephrogenic origin There

PRIMARY PERITONITIS

Primary or idiopathic peritonitis is caused by the beta streptococcus and various types of pneumococcus It is comparatively rare and while it is occasionally seen in adults, the great majority of patients are children, usually girls, less than ten years of age The three modes of entrance of the organisms generally considered are (1) the blood stream, in disease of the respiratory tract, (2) the intestinal tract by penetration from the wall of the bowel, and (3) through the uterus and fallopian tubes in infection of the vagina The blood stream seems to be the most common pathway but the viewpoint of Cole, that there is probably more than one avenue of infection, is most logical The mortality figures are extremely high for both streptococcic and pneumococcic primary peritonitis Newell in a review of the literature reports an average mortality of 80 to 100 per cent in the former and 40 to 65 per cent in the latter group

Diagnosis is not easy because of the absence of a history of an intra abdominal lesion and because abdominal pain and vomiting are prominent features of many acute diseases among children Abdominal puncture is the most important aid in diagnosis and in a series of thirty cases reported by Pollock conclusive evidence of the underlying pathologic process was obtained in all

The treatment usually advised is drainage of the abdomen It is well accepted that this should be done where localization has occurred but some such as Horsley feel that drainage in the early acute stages may be harmful In view of our more recent experiences with serum and sulfonamide therapy, it is probable that early surgical exploration with bilateral drainage in both lower quadrants of the abdomen should be employed in the majority of instances of acute pneumococcic peritonitis

In pneumococcic peritonitis, sulfonamide therapy has appreciably bettered the results of the former treatment by serum it has the added advantages of less delay in starting treatment and is less expensive than serum therapy Sulfathiazole or sulfadiazine is the drug of choice The usual oral dose for an adult is 6 Gm (90 grains) the first day subsequent doses depend on the concentration of the drug in the blood the ideal concentration being 5 to 10 mg per 100 cc. The sulfonamides may also be given intravenously as a 5 per cent solution of the sodium salt. Sulfapyridine and sulfadiazine are probably best not used locally on the peritoneum Streptococcic peritonitis has shown a much less severe course since the introduction of sulfanilamide locally on the peritoneum and the oral use of sulfathiazole. Early laparotomy and drainage have proved to be of no value in the presence of streptococcic peritonitis Conservative treatment, with the early institution of sulfanilamide therapy, seems to offer most Other supportive measures, in the form of fluids administered intravenously and frequent small transfusions of blood should be instituted as indicated

Donald C Balfour

CHRONIC PERITONITIS

By far the most common form of chronic peritoneal inflammation is tuberculous peritonitis (see *Tuberculosis*)

Chronic peritonitis is usually regional and follows recovery from acute peritoneal infection Chronic pelvic peritonitis in women is one of the more common forms of the disease Postoperative adhesions are a manifestation of a previous peritonitis A serous or fibrous form of chronic peritonitis is usually described, but most frequently both varieties are present in a single case

Other forms of chronic peritonitis such as actinomycosis, Pick s syndrome (pericarditic pseudocirrhosis), in which both the parietal and visceral peritoneum are markedly thickened and white and chronic encapsulated peritonitis are rare This last named condition is described by Maingot as the formation of a membrane which envelops portions of the small intestine and mesentery together with resulting agglutination of coils of intestine These form globular tumors which may in some cases be demonstrable The patient usually complains of recurring attacks of pain There may be slight fever and a palpable mass The condition is considered to be the result of a peritoneal tuberculosis Carcinomatosis or carcinosis are terms applied to carcinomatous peritonitis—a condition which is frequently seen as the

minor procedure it has occasionally given rise to peritonitis or other serious complications Many operations have been devised for permanent drainage of the fluid The Talma Morison operation and other types of omentopexy have been beneficial in certain cases of cirrhosis

Chylous Ascites —Ascitic fluid most often is clear and has a yellow or greenish tinge It is alkaline and has a specific gravity from 1 008 to 1 015 The albumin content is lower than that of blood serum usually being about 2.5 to 4.5 per cent and there is little tendency to coagulation on standing When the ascitic fluid has an opalescent milklike appearance as a result of the presence of chyle it is called 'chylous' ascites This is a rare condition caused by obstruction or injury to the receptaculum chyli or the thoracic duct It is most often due to nephritis elephantiasis or malignancy

While pseudochylous ascites is also rare it is more common than chylous ascites It is caused by fatty degeneration of cells or chemicophysical change of a nonfatty nature in a serous ascites of long standing The two fluids can be differentiated by chemical and physical analysis

are many retroperitoneal tumors which may secondarily involve the peritoneum One could include tumors arising from the supra renal glands kidneys, and pancreas in this group The chief retroperitoneal tumors are lipomas and sarcomas

Actinomycosis although never primary in the peritoneum, may arise secondarily and cause the formation of a tumor Echinococcus cysts may be formed in any part of the peritoneum, and they have frequently been the cause of an abdominal tumor of considerable size There are no characteristic symptoms by which the diagnosis of one of these rare conditions of the peritoneum can be recognized Many of them require no treat ment, but when treatment is necessary, it is usually surgical

DONALD C BALFOUR

ASCITES

Ascites is any collection of free fluid in the peritoneal cavity The term is usually used however, to describe a collection of a serous fluid Ascites is essentially a symptom and not a disease

Etiology—Ascites may be due to either local or general causes In the majority of cases, ascites is due to heart and kidney dis eases abdominal neoplasms cirrhosis of the liver, or tuberculous peritonitis Other forms of chronic peritonitis obstruction of the main portal vein or inferior vena cava by thrombosis enlarged lymph nodes or tumors of adjacent organs may also produce ascites Ascites is rarely seen in syphilis pernicious and aplastic anemia in the leukemias Hodgkin's disease splenomegaly associated with anemia, echinococcus disease, abscess and amyloid disease of the liver or pericarditic pseudocirrhosis of the liver (Pick s syn drome)

Symptoms—The patient will frequently mention that there has been a gradual in crease in the size of the abdomen with an associated sense of fulness and tightness There may be many general symptoms of which ascites is only a part The enlargement of the abdomen may be striking varying with the amount of fluid present There may be bulging of the flanks when the patient is recumbent or of the hypogastrium when he is upright The skin may be shining and tense and lineae albicantes may be present if the effusion is large The umbilicus may be flattened or everted The veins of the abdomen are often prominent especially around the umbilicus ('caput medusae")

When the fluid is free a fluid impulse may be obtained by striking one flank g ly and receiving the wave with the hand on the other flank A characteristic sensation of fluid displacement may be obtained by mak ing a quick dipping movement over the spleen or liver A shifting dulness on per cussion, present in the most dependent part, is the most valuable sign of ascites This is best elicited by careful percussion of the abdomen with the patient in various positions. An ordinary roentgenogram of the abdomen may occasionally be of assistance The with drawal of ascitic fluid is of course, a positive diagnosis, but at times a dry tap may be obtained owing to the presence of adhesions

Diagnosis—The diagnosis is based chiefly on examination of the abdomen and para centesis Ascites must be differentiated from all conditions which cause enlargement of the abdomen among which are gaseous distention ovarian cyst pregnancy distended bladder obesity and fluid hemoperitoneum. In a few cases in which the ascitic fluid is loculated by adhesions within the peritoneal cavity, it may be necessary to perform surgical exploration before a diagnosis can be made

Treatment—A patient having ascites *per se* should not be treated for an indefinite period without an understanding of the causative background Diagnostic laparotomy or peritoneoscopy as proposed by Ruddock and others may be necessary to establish this causative background When this has been established the treatment should be directed primarily toward the underlying cause which will be discussed in separate sections Certain general measures such as rest in bed limitation of the intake of fluid and a diet high in carbohydrates are beneficial Diuretic drugs such as ammonium chloride ammonium nitrate calcium chloride and certain organic mercury compounds are indicated in many instances The chief surgical procedure is removal of the ascitic fluid by a trocar (paracentesis abdominalis) While this is considered a

alone cannot differentiate between a sinus infection that is active and one that is clinically cured The history, the presence of a discharge in the nose the x ray plate and when possible irrigation of the suspected sinus may all be necessary to establish diagnosis

Treatment—Sinus infections are local manifestations of infection of the respiratory tract With the general therapy suitable for such an infection the local application of heat and the use of astringents in the nasal passages usually relieve the acute symptoms Nasal irrigations often cause aural infection and mastoiditis If the pain of acute sinusitis is very severe the patient should be referred to a rhinologist without delay because this usually precedes the onset of complications Chronic infections usually require special surgical treatment which favors better drainage

Infections of the Accessory Nasal Sinuses in Children—With the exception of the frontal sinuses the accessory nasal sinuses are well developed at an early age Sinusitis not infrequently complicates the exanthemata Children who are subject to recurring respiratory infections often have foci in one or more nasal sinuses Local treatment consisting of astringent and antiseptic nasal drops as well as gentle suction or irrigation will clear up many of the milder infections The removal of infected tonsils and adenoids is regularly indicated More rarely improved drainage by conservative surgery will be necessary It is of the utmost importance that any associated dietary deficiency or allergy be discovered and properly treated

Complications of Sinus Infection—Extension of the nasal infection to neighboring structures such as the eyes ears throat or tracheobronchial tree is commonly observed Alarming and often fatal intracranial invasion may also occur in the form of *meningitis cavernous sinus thrombosis epidural* or *frontal lobe abscess*

Osteomyelitis is a most important complication and may be precipitated by trauma or sinus surgery The fulminating variety is frequently followed by involvement of the meninges or brain by way of a widespread thrombophlebitis Edema of the soft tissues with characteristic doughy swelling is the outstanding clinical manifestation Radical removal well into the healthy surrounding bone is imperative in these cases

An orbital cellulitis or *abscess* may complicate an infection of the frontal or ethmoid sinuses especially in childhood Edema usually improves with conservative treatment but external drainage is indicated by the presence of exophthalmos with limitation of motion Needless infection of the orbital contents by premature incision must be carefully guarded against

Retrobulbar neuritis in the past has been frequently attributed to a posterior sinusitis because of rapid improvement following sinus surgery Accumulated evidence however has raised grave doubts concerning the frequency of this causal relationship Multiple sclerosis is the accepted cause of the majority of these disturbances and hasty surgical intervention is to be avoided

The frequent association of sinusitis with chronic diseases of the tracheobronchial tree—especially bronchiectasis as well as certain cases of asthma—has become well established Proper treatment of the nasal infection is imperative in these cases

Clyde A Heatly

TUMORS OF THE NOSE AND NASOPHARYNX

New growths starting in the nasal passages are not infrequent in children Fibroma and spindle-cell sarcoma are the common types The *nasopharyngeal fibroma* or *juvenile polyp* causes pressure necrosis of the bony structures and may invade the orbit or cranial cavity it occurs only in males between the ages of ten and twenty five years On account of the great vascularity of these tumors radium therapy gives the best results

In adults *sarcoma* is relatively rare in the nose but is common in the nasopharynx *Carcinomata* seldom cause obstruction because of early ulceration Sarcoma gives rise to large tumors and obstruction is one of the early symptoms of this type of growth

Enlargement of the cervical glands may be the first sign of a nasopharyngeal growth although obstruction to breathing a blood stained nasal discharge or ringing in the

DISEASES OF THE RESPIRATORY SYSTEM

DISEASES OF THE NOSE

UNDER normal conditions air is warmed, *moistened*, and cleansed during its passage through the nose The mucous membrane of the nose is continuous with that lining the accessory nasal *sinuses* and *is everywhere* rich in mucous glands If the nasal passages are obstructed by deflection of the septum, by hypertrophy of the mucous membrane of the turbinates or by enlarged adenoids, the mucous glands may be stimulated to increased activity and chronically produce a catarrhal discharge This catarrhal process may by spreading to the mucous membrane of the eustachian tube, *lead to changes in the middle* ear that result in impairment of hearing Obstruction of the nose favors pyogenic infection of the accessory nasal sinuses with such resulting symptoms as headache chronic discharge of purulent material much of which is swallowed and the general disorders associated with focal infection

Epistaxis is usually due to superficial ulceration of the anterior part of the septum *Hypertension however may* cause rupture of the vessels in the posterior part of the nose and profuse hemorrhage Hereditary multiple telangiectasis permits repeated hemorrhage that may lead to profound anemia The telangiectatic areas in the nose and nasopharynx bleed more easily than those on the mucous membranes of the mouth or tongue A blood stained nasal discharge in a child always suggests enlargement *and infection of the adenoids nasal* diphtheria the presence of foreign body, or congenital syphilis in adults it is frequently evidence of a new growth

CLYDE A HEATLY

INFECTIONS OF THE ACCESSORY NASAL SINUSES

Etiology—The most common cause of infection of the accessory *nasal sinuses is acute rhinitis Abscesses* at the roots of the upper bicuspid and molar teeth often rupture into the maxillary sinus and produce infection which *may give rise to no symptoms* other than a chronic unilateral nasal discharge Sinusitis may result from swimming or diving Trauma allergy and dietary deficiencies are important predisposing factors

Symptoms—The nasal communications of the accessory nasal sinuses are narrow and easily obstructed by the edema and discharge of thick mucus that accompany acute *inflammation This obstruction gives rise to* headache, which is the most characteristic symptom of acute sinusitis The mucous membrane of the nasal passages and accessory nasal sinuses is innervated by the trigeminus nerve, and the pain of sinus infection is most commonly referred to the area of distribution of this nerve Infection of the sphenoidal sinuses however may give rise to suboccipital discomfort

The headache or pain of sinus infection in contrast to that of hypertension intracranial growths neurasthenia and eye strain is usually limited to the face The pain of an acute infection of the frontal or maxillary sinus is usually localized over the affected sinus Chronic infection however particularly of the maxillary sinuses is *often* accompanied by discomfort over the forehead on the same side Infection of an ethmoidal *sinus usually causes* discomfort in the orbit or across the bridge of the nose Occasionally the pain of a sinus infection is referred to the mastoid region a fact explained by the innervation of the mucous membrane lining the mastoid cells by the trigeminus In acute sinusitis the pain may be constant, *but in the chronic condition* it is characteristically more severe in the forenoon and disappears toward evening

Diagnosis—Severe acute coryza or more general infection such as influenza or pneumonia is usually responsible for infection of an accessory nasal sinus From 15 to 40 per cent of *all infections* of the maxillary sinus are of dental origin X ray shadows

are so strikingly similar that a final diagnosis frequently depends on the results of this direct examination as well as on the cultures thereby made possible from the larynx itself The spasmodic form of acute laryngitis (*croup*) differs from the more common acute catarrhal inflammations in its characteristic nocturnal episodes of harsh metallic cough and often alarming inspiratory stridor and dyspnea which are relieved by steam inhalations and emetics and leave few residual symptoms the following day Acute infections of the larynx are so frequently complicated by varying degrees of obstruction that special consideration should be given to this difficult problem The picture of *obstructive laryngeal dyspnea* should be completely familiar to every physician for while the increase of dyspnea may be gradual the transition to terminal asphyxia and collapse in childhood may be alarmingly sudden The child is restless and anxious Respirations are rapid labored and accompanied by a harsh inspiratory stridor Pallor is more common than cyanosis The progress of the obstruction can best be followed by observing the degree of retraction about the thoracic cage for with progressing dyspnea increasing retraction is noted in the suprasternal notch the supraclavicular fossae the intercostal spaces and the epigastrium Cyanosis and apathy usually denote terminal exhaustion Atropine which thickens secretions and opiates which depress the respiratory center must never be administered to these dyspneic patients

Tracheotomy through the second or third tracheal rings should be carried out under local anesthesia in the presence of progressive and well established evidences of laryngeal obstruction This procedure not only insures a proper airway and puts the inflamed larynx at rest but also permits suction drainage of the profuse tracheal secretions which frequently complicate many of these cases and thereby constitute a continued source of danger from low obstruction (acute laryngotracheobronchitis)

Congenital laryngeal stridor is characterized by the onset of stridor shortly after birth The stridor is chiefly inspiratory is aggravated by crying and tends to diminish or disappear during nursing or sleep The voice sounds are unchanged and cyanosis is seldom observed This disturbance is caused by the vibrations of an elongated epiglottis as well as by the flabby structures of the upper rim of the larynx and gradually disappears with the normal growth of the larynx usually during the second year of life

Laryngismus Stridulus (*Laryngospasm*) —Laryngismus stridulous in children may be defined as a laryngeal stridor of sudden onset without fever It is rare during the first three months of life and most common in children from six months to two years of age Boys are more frequently affected than girls It is uncommon in breast fed infants and is nearly always associated with rickets The laryngeal spasm is a manifestation of the extreme irritability of the nervous system in tetany

Symptoms—An attack is characterized by the sudden onset of inspiratory dyspnea without premonitory symptoms Obstruction may be so marked as to cause temporary complete apnea with deepening cyanosis unconsciousness convulsions or death may follow in severe cases Usually however after fifteen or twenty seconds a characteristic deep inspiration shows that the glottic spasm has relaxed There may be numerous subsequent attacks The child may be normal between attacks or may show other evidences of tetany

Diagnosis—The age of the patient the absence of fever the periods of apnea followed by a characteristic crowing inspiration and the associated clinical signs of tetany (carpopedal spasm Chvostek s and Trousseau s signs etc) are pathognomonic Since a foreign body lodged in the larynx may however produce almost identical symptoms the larynx should be directly examined through a laryngoscope

Treatment—During the attack artificial respiration and cold applications to the face and chest are most effective Intubation and tracheotomy are rarely necessary Later the fundamental metabolic disturbances must be treated

Foreign Bodies in the Larynx—The sudden onset of paroxysms of coughing and dyspnea in a healthy child suggests the presence of a foreign body in the larynx trachea or bronchi Immediate tracheotomy may be necessary Metallic bodies such as coins may be localized with the fluoroscope Since less

ear may be the initial symptom Of 70 patients whose cases were reported from the Mayo Clinic only 38 had nasal symptoms Invasion of the pterygoid fossa with fixation of the jaw, pain or anesthesia in the area of distribution of the second or third division of the trigeminus, invasion of the orbit with paralysis of certain of the extraocular muscles or severe and constant headache from meningeal irritation are all common manifestations of malignant growth in the nasopharynx

Pyogenic infection of the accessory nasal sinuses is usually associated with all new growths arising in the nose Similarly infection of the ear commonly accompanies new growths arising in the nasopharynx

The removal of a piece of growth for microscopic examination may be necessary to establish diagnosis but encourages secondary infection which often leads to frequent and profuse hemorrhage

Treatment —On account of the anatomic relations, complete surgical removal of a malignant growth is seldom possible and irradiation is the most desirable therapeutic measure

DISEASES OF THE LARYNX

INTRODUCTION

Stridor as a symptom may afford valuable clinical evidence as to the location of the lesion *Inspiratory stridor* is particularly common in children and suggests laryngeal diphtheria a foreign body, papilloma of the larynx, spasm or incoordination of the muscles of the glottis—as in laryngismus stridulus Almost any laryngeal irritation in a child may cause a glottic spasm the most frequent manifestation being the crowing inspiratory stridor of catarrhal laryngitis (croup) *Expiratory stridor* suggests an obstructive lesion in the trachea or bronchial tree This may be due to an inflammatory condition as tracheal diphtheria to asthma or pneumonia or to pressure from mediastinal tumors Aneurysm is the most common cause of expiratory stridor in adults, while pressure due to tuberculous glands is frequently provocative of this symptom in children It is important to emphasize that no patient with a marked stridor should be submitted to general anesthesia A patient with stridor is forced to use all his accessory respiratory muscles and a general anesthetic is liable to make the respirations cease abruptly

Early and frequent examinations of the larynx are important in the three following conditions (1) Pulmonary tuberculosis predisposes to catarrhal changes in the larynx tuberculous laryngitis is an important complication and if recognized in its early stage, may be cured by well-directed measures. (2) The recurrent laryngeal nerves are in close approximation to the posterior capsule of the thyroid gland and may be injured by pressure exerted by an enlarged thyroid as well as by operative procedures on this gland For this reason every patient with goiter should have a laryngeal examination both *before* and *after* operation The prognosis of an operative lesion of the recurrent laryngeal nerve is favorable provided the onset of the hoarseness is gradual and not immediate (3) Hoarseness when persisting in a patient over forty for more than three weeks is often due to cancer If recognized early the prognosis after operative removal and irradiation is good If however examination is postponed until the appearance of evident clinical symptoms of malignancy a cure rarely results from any method of treatment

CLYDE A HEATLY

COMMON LARYNGEAL DISORDERS IN CHILDREN

Acute Laryngitis —The larynx in infancy and childhood is characterized by its relative smallness its unusual irritability and its tendency to dangerous edema as the result of acute infections or instrumentation Direct laryngoscopy is essential to accurate diagnosis and is a most important advance over the inferential methods of former years The clinical manifestations of nondiphtheritic and diphtheritic infections

side is a common symptom of tuberculous laryngitis in the ulcerative stage

Treatment —The larynx of patients with pulmonary tuberculosis should always be examined at frequent intervals The onset of hoarseness demands immediate laryngoscopy and enforced silence The use of the electro cautery is generally recognized as the most important measure in local treatment It is used at white heat to avoid bleeding It is contraindicated in patients with high fever or very active pulmonary lesions Light ther apy as well as the local instillation of chaul moogra oil (20 per cent) has been employed for its palliative effects with varying success Dysphagia may often be relieved by injec tion of alcohol into the superior laryngeal nerve Tracheotomy is seldom indicated ex cept for stenosis or rapidly developing edema

Syphilitic Laryngitis —The gumma which is the common syphilitic lesion of the larynx is usually situated above the vocal cords on one side It is composed largely of dense fibrous tissue and unless it ulcer ates produces no symptoms other than hoarseness and slight stridor If ulceration takes place the resulting scar tissue usually causes marked deformity and stenosis of the larynx Laryngeal lesions associated with those of the mucous membrane of the pharynx in secondary syphilis may produce symptoms identical with those of acute catarrhal laryngitis Acute laryngitis which does not respond to treatment within a reasonable time should arouse suspicion of syphilis Simultaneous occurrence of both secondary and tertiary lesions in the throat is not uncommon

Diagnosis —The conditions to be differen tiated are *tuberculosis* and *new growths* The diagnosis depends largely on the evi dence of syphilis elsewhere in the body although it must be emphasized that tuber culosis and syphilis as well as cancer and syphilis are often associated

Treatment —Gumma of the larynx is very resistant to any general or local antisyph ilitic therapy and unless the local symp toms are urgent local laryngeal treatment is probably undesirable Injury to a gumma such as cauterization or excision of a piece for diagnosis encourages secondary infec tion and ulceration The secondary lesions in the throat and larynx are best treated intra venously

Benign and Malignant Tumors of the Larynx —**Benign Tumors** —The most common of the benign tumors in the larynx are the polyp and the papilloma The papilloma of the larynx in adults differs from that in children in that it is usually solitary and shows far less tendency to recur after removal, furthermore it is fre quently of tuberculous or syphilitic origin The symptoms of a laryngeal growth depend upon its location The long pedunculated polypi that grow on the vocal cords cause attacks of paroxysmal coughing and hoarse ness due to interference with accurate ap proximation of the vocal cords Benign growths seldom cause bleeding pain or dys phagia They are best treated by local ex cision through the mouth although local application of radium often causes complete disappearance of the more vascular type

Malignant Tumors —*Carcinoma* is al most the only malignant growth in the larynx in the trachea and bronchi sarcoma is common The point of origin of carcinoma is of considerable importance If it arises on a vocal cord the tumor is usually situated on the anterior half A tumor in this situa tion is termed intrinsic and is relatively benign If the growth involves the mucous membrane over the arytenoid cartilages or the lateral walls of the larynx above the vocal cords it is said to be an 'extrinsic growth and the prognosis is bad A carci noma that arises from the posterior wall of the larynx just above the opening of the esophagus is the most malignant of all laryngeal growths

Diagnosis —It is of the utmost impor tance to recognize carcinoma of the larynx early because only then can a cure be ef fected without recourse to radical mutilat ing surgery From 75 to 85 per cent of car cinomas of the larynx develop in males be tween the ages of forty and sixty The earliest symptom of a growth on a vocal cord is hoarseness when this appears in an individual forty years old or more it should be regarded as due to carcinoma until proved otherwise As differentiation of a malignant from a benign growth is often difficult at this early stage it may be neces sary to remove a piece of tissue for micro

opaque bodies, such as fish bones may not be demonstrable by the x ray, direct examination of the larynx and trachea is necessary In children all examinations should be conducted without anesthesia

Papilloma of the larynx in children, although benign has a mortality almost equal to that of carcinoma of the larynx in adults Fortunately, it is relatively rare, only twenty cases having been seen at the Johns Hopkins Hospital from 1912 to 1924 It may appear at any age and is much more common in boys

The exact *etiology* is uncertain, although experimental studies in Vienna suggest that an invisible, filtrable virus is the direct cause Both in structure and behavior the lesion resembles that of verruca vulgaris of the skin Even very slight trauma may cause implantation of new growths on the surrounding mucous membrane

Symptoms—The symptoms depend on the size and location of the tumor Slowly developing but progressive hoarseness, a paroxysmal cough and at a later period dyspnea, should excite suspicion of laryngeal growth

Diagnosis—Direct inspection of the larynx (without anesthesia) is necessary for positive diagnosis

Treatment—Simple removal of the tumor rarely results in cure but on the contrary usually stimulates further growth Repeated removal of the recurring growths and long continued general hygienic measures are required to cure this condition Early tracheotomy may be necessary The improved methods of fractional irradiation may prove helpful

CLYDE A HEATLY

COMMON LARYNGEAL DISORDERS OF ADULTS

Catarrhal Laryngitis—*Acute catarrhal laryngitis* is usually secondary to infection of the upper respiratory tract but may be brought on also by irritation from improper use of the voice as well as by excessive use of alcohol or tobacco or by chemical fumes The lesions in the larynx vary from slight subglottic hyperemia and edema to diffuse reddening of all the mucous membranes of the glottis and shallow ulceration Hoarseness is the most constant symptom but in the more acute condition there may be aphonia and a dry burning sensation in the throat Catarrhal laryngitis is differentiated from tuberculous laryngitis by the absence of pulmonary symptoms *true tuberculous laryngitis is always secondary to a pulmonary lesion* The *treatment* consists in abstinence from speaking with cold applications, benzoin inhalations regulation of the surroundings so that the air is moist and of even temperature, and rest

Chronic catarrhal laryngitis is due to long continued irritation from any of the causes of the acute condition The pathologic change which is usually most prominent in the posterior half of the larynx consists of thickening of the epithelium This condition was originally described by Virchow as *pachydermia* and is not to be confused with carcinoma The other lesions involve the vocal cords and the intrinsic muscles In the larynx as in the nose and nasopharynx, chronic irritation causes excessive secretion of thick glairy mucus which produces many of the symptoms of chronic laryngitis The cause of such chronic discharge from the upper air passages especially in pyorrhea chronic tonsillitis or sinusitis demands proper treatment Any excessive growth of epithelium between the posterior ends of the cords should be removed

Tuberculous laryngitis is always secondary to pulmonary disease The improved methods of diagnosis and treatment of pulmonary tuberculosis especially the increasing use of collapse therapy have greatly reduced the incidence of laryngeal complications Dworetzky reports an incidence of only 3 6 per cent in 500 cases in 1941 as compared with 25 6 per cent in a similar series in 1914 Wilson states that the incidence in minimal pulmonary disease is now less than 5 per cent and not more than 20 per cent in far advanced infections The earliest specific changes in the form of hyperemia and infiltration are usually localized in the posterior half of the larynx particularly in the interarytenoid sulcus Later changes include marked edema especially of the arytenoids or epiglottis ulceration of the vocal cords the formation of tuberculomas perichondritis or fibrosis Pain on swallowing often radiating to the ear on the same

pathogenic as for instance the pneumococcus

Etiology—Bronchitis is highly contagious and such bacteria as the streptococcus pneumococcus influenza bacillus *Micrococcus catarrhalis* and staphylococcus are commonly present in the bronchial secretions Whether or not these are the primary factors in the etiology of the disease has not been established It seems probable that a filtrable virus such as Dochez has demonstrated in connection with acute coryza is usually the initiating factor such a virus in the nose and throat presumably renders the bronchial mucosa susceptible to the secondary implantation of such organisms

Sporadic cases occur but it may be epidemic Not infrequently an entire household is affected many cases follow indoor crowding Chilling of the body seems to be a predisposing factor, perhaps by lowering body resistance but other factors including probably the specific virus must also be present It is most common in the spring and fall when the weather is changeable It predominates in very young children particularly under 3 years of age in the aged and in those greatly debilitated by other disease Some individuals seem to be especially predisposed to bronchitis and in them the slightest exposure may bring on an attack this may be due to some allergic factor In this connection it is recognized that the inhalation of dust will precipitate an attack in some persons

Acute bronchitis may occur as a feature of certain infectious diseases especially typhoid fever It also occurs as one of the manifestations of measles of whooping cough and of asthma The bronchitis of an asthmatic may be on an allergic basis and therefore a primary feature of the asthma or it may be the result of an intercurrent infectious agent Not infrequently an acute bronchitis is associated with hypertrophied tonsils and adenoids in children and often it is secondary to an infected sinus It may result from certain noninfectious agents as from the inhalation of poisonous gases or from the aspiration of irritant liquid or solid material

Morbid Anatomy—The involvement is usually bilateral although it may be more marked on one side than the other The mucous membrane is inflamed and covered with an exudate of sticky, grayish mucoid character sometimes mucopurulent and when influenza is associated hemorrhagic Patches of epithelial desquamation are observable but no ulceration The smaller tubes may be dilated The submucosa is usually edematous and infiltrated with leukocytes The mucous glands are swollen

Symptoms—The symptoms of this affection may come on abruptly but more frequently are preceded by the manifestations of an acute coryza or sore throat The larynx as indicated by hoarseness may be affected from the first When the trachea and bronchi become involved chilliness lassitude and soreness in the muscles of the back and extremities are usually the earliest complaints Later as the inflammation extends farther down the bronchi a sense of retrosternal soreness or tightness is felt A chill is rare but may occur at the onset in children Even in severe cases the temperature rarely exceeds 101° to 102° F and it commonly subsides within four or five days if it lasts longer than a week bronchopneumonia should be suspected The pulse is proportionately increased except in the influenzal cases The respiratory rate also increases with the temperature but if disproportionately increased some pulmonary complication must be suspected Cough develops almost at once and at first is dry rough and ringing After a day or two it becomes softer and productive of a scanty viscid material which is expelled with difficulty still later of a more profuse and mucopurulent or even purulent sputum The cough often persists for two to three weeks although the discomfort usually subsides with the fever

Physical Signs—No physical signs may be demonstrable over the chest this is particularly true as long as only the trachea and large bronchi are involved If however the medium sized bronchial tubes become affected rales may be heard bilaterally especially over the basis of the lungs posteriorly at first they are dry then moist and bubbling They may appear and disappear and change in their character and location frequently and are commonly associated with some roughness of the inspiratory and expiratory breath sounds When the signs are

scopic examination Extrinsic growths often ulcerate early, so that there may be bleeding and pain on swallowing The location of the earliest metastases of carcinoma of the larynx is in the deep cervical glands about the bifurcation of the common carotid artery

Tuberculosis syphilis cancer and *benign growths* may cause diagnostic confusion The age of the patient the appearance of the larynx and the result of general physical examination must all be taken into consideration before arriving at a final diagnosis Not infrequently a patient with cancer of the larynx is found to have a positive Wassermann reaction in such cases there is danger of continuing antiluetic treatment until the growth has become inoperable It is not unusual also to find both tuberculosis and carcinoma in a cervical gland removed for diagnosis

Treatment —Early removal of an *intrinsic carcinoma* and the affected cord results in a high percentage of cures In more advanced cases total laryngectomy is necessary *Extrinsic growths* are best managed by the improved methods of irradiation

Laryngeal Neuropathies —The muscles* that move the vocal cord are innervated by the recurrent laryngeal nerve a branch of the vagus This is frequently involved in pathologic processes and hoarseness results The common cause of *a recurrent nerve palsy* is an aneurysm of the arch of the aorta Other cases are a mediastinal growth tuberculosis of the apex of the right lung implicating the pleura dilatation of the left auricle as in mitral stenosis carcinoma of the esophagus and thyroid and metastasis and inflammation of the glands in the neck that involve the vagus Postdiphtheritic and syphilitic neuritis may also cause laryngeal palsies There are too so called *functional laryngeal palsies* which may be distinguished from the organic type by the sudden onset of complete aphonia without loss of ability to cough and laugh and by the movements of the vocal cords revealed by the laryngeal mirror

The recurrent nerve lies close to the posterior capsule of the thyroid gland and the onset of hoarseness following thyroidectomy indicates that it has been injured If the nerve is divided, hoarseness ensues immediately and may never entirely disappear If the hoarseness comes on gradually however it may be due to stretching or edema of the nerve, and the voice will ultimately return to normal If, during operation both nerves are injured but not divided inspiratory stridor develops suddenly because of inability of the cords to open during inspiration Temporary tracheotomy may be necessary

The *prognosis* for complete restoration of function following postdiphtheritic paralysis is good The laryngeal crises of tabes are really glottic spasms depending on syphilitic neuritis of the recurrent nerves For this condition also tracheotomy may become necessary since antiluetic therapy is not always effective

DISEASES OF THE BRONCHI

BRONCHITIS

BRONCHITIS is strictly speaking an inflammation of the bronchial tubes Practically however the trachea is usually involved in the inflammatory process though the tracheitis may give rise to no additional symptoms or physical signs and requires as a rule no additional treatment The term tracheobronchitis is therefore more descriptive of the total pathologic process

Acute Bronchitis —Acute bronchitis may be primary and develop independently but usually it is secondary as when it follows or is associated with such conditions as an acute cold measles whooping cough or influenza It is of serious importance chiefly because of its most frequent complication pneumonia Acute bronchitis may serve to arouse a latent tuberculous infection of the lung or it may lower local resistance and so lead to infection of the lung by organisms frequently present but otherwise non

disease particularly when the maxillary sinuses are involved Not uncommonly it is associated with or secondary to some chronic pulmonary disease such as bronchiectasis interstitial pneumonia tuberculosis or pneumonoconiosis or the pulmonary congestion that results from cardiovascular disease Emphysema often dominates the clinical picture and asthma is frequent Gout and renal disease are said to be associated with some cases probably because of the coincident circulatory disturbance Aortic aneurysm and enlarged tracheobronchial lymph glands may be factors in its production Excessive smoking syphilis and alcoholism may be predisposing influences The long continued inhalation of inorganic dusts such as occur in stone cutters coal miners potters and grinders of metallic substances apparently gives rise to a primary form of the affection Chronic bronchitis usually occurs in older people mostly in males and in them it is commonly associated with bronchiectasis It is more common in winter and so is sometimes spoken of as the winter cough of the aged It may however occur in children especially in those who have hypertrophied tonsils and adenoids and in those with rickets or paranasal sinus disease

Morbid Anatomy—There is venous hyperemia of the bronchial mucosa with hypertrophy of the membrane in some instances and atrophy in others some longitudinal bands of elastic tissue may be visible and in places denudation of epithelium Ulceration is rare but atrophy of the muscular and glandular elements with eventual dilatation of the tubes often occurs Some chronic peribronchitis may be present causing thickening of the walls Emphysema is common The sputum is usually scanty but may be profuse it contains mucus epithelium and pus cells

Symptoms—The general health is little impaired fever is rare and pain is usually absent Cough is the outstanding symptom and it varies with the season of the year the time of day and the degree of physical activity It may occur only in the winter months at least it is more troublesome during that season Frequently it is worse at night or in the early morning and is exaggerated by physical exertion It may be periodic or paroxysmal and is usually relieved by expectoration of the bronchial secretions The sputum too is variable it may be scanty and very mucoid or quite profuse and mucopurulent or purulent, if it is offensive in odor bronchiectasis or abscess of the lung should be suspected When chronic pulmonary or cardiac disease is associated dyspnea on exertion is a prominent symptom when emphysema is present the shortness of breath is usually worse at night

Physical Signs—The physical signs of chronic bronchitis resemble those of the acute form consisting chiefly of moist rales of varying sizes throughout the chest additional signs due to associated conditions most often emphysema are frequently present The chest therefore is prone to be barrel shaped with hyperresonance and diminished expansion The cardiac apex beat is frequently not visible Dyspnea and cyanosis are common The rales are bilateral and generally distributed but most numerous at the posterior bases and usually coarse and of a sonorous or bubbling character When the bronchitis is in abeyance no rales may be audible The breath sounds may be feeble with a prolonged wheezy expiration

Diagnosis—As in the acute form care must be taken to eliminate other more serious conditions before accepting the diagnosis of chronic bronchitis Although pulmonary tuberculosis is not so frequently confused with this form as with acute bronchitis sputum examinations for tubercle bacilli should always be made Even in elderly patients not seriously ill with no special signs at the apices and no fever tuberculosis of the lungs will sometimes be discovered The character of the sputum and clubbing of the fingers will often serve to differentiate cases of bronchiectasis Roentgenologic study is always indicated and will not infrequently reveal bronchiectasis tuberculosis an unsuspected foreign body or advanced pneumoconiosis

Prognosis—The prognosis is hopeful in the young but beyond middle life few recover though they may never be seriously incapacitated by the disease Acute exacerbations are common and emphysema and bronchiectasis not infrequently result The mere presence of chronic bronchitis may be

confined to one side of the chest some other and more serious condition must be suspected

Diagnosis—The chief conditions to be considered in the differential diagnosis are pulmonary tuberculosis bronchopneumonia, asthma typhoid fever bronchiectasis measles and whooping cough In children the presence of foreign bodies in the bronchi and of mediastinal lymphadenitis must be given some thought The failure to remember that the symptoms and signs of these diseases frequently mimic those of simple acute bronchitis is responsible for most of the errors in diagnosis Many of these conditions can soon be recognized by the appearance of other signs and by the course of the disease If the cough lasts more than three or four weeks if the fever lasts more than a week and is of the afternoon type and if a loss of weight and malaise are associated tuberculosis must be suspected and roentgenologic studies made Bronchopneumonia as already indicated may be suggested by a disproportionate increase in the pulse and respiratory rates also by a sudden increase in the fever leukocytosis profound intoxication a preponderance of rales in one side of the chest or the development of additional and characteristic physical signs Radiologic and bronchoscopic studies may be necessary to eliminate such conditions as bronchiectasis or foreign body Whooping cough may not be distinguishable until the characteristic inspiratory whoop develops measles is usually recognized by its appearance in a child in the midst of an epidemic by the inflamed nasal and conjunctival membranes and by Koplik s spots

Prognosis—The prognosis of acute bronchitis as such is always good Because however of the frequency of bronchopneumonia as a complication particularly in young children and in elderly people caution in predicting the outcome is wise Serious consideration must be given to persons who have an arrested or quiescent tuberculous lesion

Treatment—Preventive measures are of great importance Children and all those who are especially susceptible should avoid contact with known cases of acute 'cold or bronchitis and exposure to cold without proper clothing to overheated and excessively dry indoor air and to indoor crowding Children with hypertrophied tonsils and adenoids should have them removed Infected persons should be isolated through the febrile stage of the disease and should have their sputum destroyed

Once the signs of the disease are manifest it is best to insist that the patient be put to bed in a well ventilated room and kept there until the fever has subsided. That is the most important part of the therapy it shortens the course of the disease and usually prevents complications Many patients are overtreated with drugs A thorough purge in the very beginning however and a mild sweat induced by a warm bath and hot drinks tend to shorten the course of the disease Fluids should be forced and only the simplest foods taken during the first day or two Dover s powder in small repeated doses (0 01–0 03 Gm) not only aids in the production of sweating but tends to relieve myalgia It acts more effectively if combined with small amounts of salol and acetophenetidin

Counterirritation over the anterior chest by means of a mustard plaster may help to liquefy the bronchial secretion Steam inhalations especially with benzoin also may accomplish this result but Hollinger considers that inhalations of 10 per cent CO in oxygen are even more effective The expectorant drugs such as ammonium chloride and terpin hydrate are said to help only in the liquefaction of the secretion of the main bronchi When the secondary infection is predominantly streptococcal pneumococcal or staphylococcal in nature the sulfonamides may bring about rapid improvement In the recurrent cases autogenous vaccines should be given a trial

If the patient lives in the city it is often helpful when the febrile stage has passed, for him to seek the seashore where he can be out of doors and in the sunshine This frequently cuts short the duration of the disease

Chronic Bronchitis — *Etiology* — The chronic form of bronchitis although associated with the same bacterial organisms as the acute variety rarely if ever develops from a single acute attack and it is doubtful if it often follows repeated acute attacks Seldom is it a primary affection It may be secondary to long continued paranasal sinus

volved in the morbid process thus constituting bronchopulmonary spirochetosis The specific bacteria were first demonstrated in bronchiectasis by Leyden and Jaffe in 1867 Their pathogenic significance was not realized however until 1905 when Castellani described two patients presenting symptoms suggestive of tuberculosis but in whose sputum the fusospirochetal organisms were found to be abundant For many years after that the disease was thought to be confined to the tropics Work in this country and France during the last few years however shows spirochetal infection of the bronchi and lungs to be surprisingly frequent.

Etiology—The disease is apparently quite contagious The causative organisms are frequently found in the mouth especially when advanced dental caries and pyorrhea alveolaris are present and they doubtless gain entrance to the bronchi from this source This may occur during inhalation anesthesia This spirochetes are apparently of several varieties The commonest type is thin and delicate with small uniform coils others are thick and long with irregular coils often one end is blunt while the other is pointed Chevalier Jackson has observed ulcers in the bronchi from which such spirochetes could be isolated

Morbid Anatomy—Superficial necrosis of the bronchial mucosa with early involvement of the elastic tissues results from the destructive action of the organisms As this tissue sloughs away deep ragged ulcers are left behind Blood vessels are eroded and bleeding occurs Dilatation of the bronchial wall eventually develops and unless their progress is arrested the organisms penetrate the adjacent lung Under such circumstances an abscess containing putrid necrotic material may develop and terminate in cavity formation or if the process is arrested in fibrosis Thus spirochetal bronchitis may lead to bronchiectasis lung abscess diffuse pneumonitis or gangrene Pleural effusion with the presence of spirochetes in the fluid has been reported

Symptoms and Signs—The disease may assume an acute or a chronic form When *acute* the onset is sudden with a chill and an irregular fever develops then cough and the expectoration of bloody and usually fetid material Fine diffuse rales suggestive of pneumonia may be present but the dyspnea is less The condition of the patient may improve within a few weeks but relapses frequently occur The *chronic* form sometimes follows the acute but may be insidious in onset and without fever Cough is present and usually is most severe in the morning, the sputum is abundant mucopurulent, often blood streaked and usually fetid Small hemoptyses may occur The course of the disease is often quite prolonged even for years A loss of weight and strength is common Tuberculosis is simulated not only by the symptoms but also by the physical signs The latter however are more often confined to the bases of the lungs especially to the right lower lobe Eventually one or more of the pulmonary complications may develop and terminate the case

Diagnosis—The diagnosis is made by the finding of large numbers of fusospirochetal organisms in the sputum Smears must be stained and examined immediately after collection since the organisms are quickly autolyzed Ordinary dyes do not stain them deeply so unless special stains are used great care must be taken in the microscopic examination Repeated examinations of the sputum are necessary in order to eliminate the presence of tubercle bacilli

The roentgenologic picture in chronic cases resembles that of tuberculosis and cannot be distinguished from it unless the lesions occur in the lower lobes In acute cases with lung involvement the roentgen ray shows a central shadow usually in the region of the hilum The shadow is not as definitely circumscribed as that of an ordinary lung abscess Rapid excavation with central cavity formation may be detected by repeated examinations There is seen also a tendency for multiple small cavities to form early with later coalescence into one large excavation

Prognosis—Death may occur with the development of some pulmonary complication Cure may be spontaneous but usually results from specific treatment

Treatment—Arsphenamine is specific in the treatment of spirochetal bronchitis and of bronchopulmonary fusospirochetal infection It is most frequently given as neoarsphenamine in intravenous doses of 0 6 Gm The symptoms physical signs and

indicative of a failing circulation with its serious possibilities

Treatment—The treatment resolves itself primarily into that of the underlying causative process whether that be chronic paranasal sinus infection, bronchiectasis rickets asthma, emphysema or other pulmonary disease or some cardiac condition Recurrent respiratory infections should be guarded against and the inhalation of harmful especially silicious dusts should be avoided Smoking should be stopped The general condition of the patient should be given special consideration and when possible residence in a mild equable climate is desirable, especially for elderly patients Much fresh air sunshine and nutritious food are indicated Rest is important and all strenuous physical exertion must be avoided The milder forms of exercise such as golfing are often beneficial

Drugs are of relatively little value in the condition and need be used only for special symptoms For the cough when excessive simple cough mixtures containing a little codeine or a bromide may be indicated in the paroxysmal cases potassium iodide is often of great value

Creosote in cases with putrid foul sputum is both bacteriostatic and deodorizing Autogenous vaccines deserve a trial in resistant cases and Jackson advises their use combined with bronchoscopic aspirations in the intractable purulent cases Holinger states that the expectorant drugs are helpful in liquefying the secretion in the first and second divisions of the bronchi but that to accomplish this result in the peripheral branches hyperemia and an increase in the rate and depth of the respirations is necessary These conditions he claims are best brought about by frequent inhalations of CO_2

Bronchiolitis Fibrosa Obliterans—This type of bronchitis originally described by Lange in 1901 is chiefly of pathologic interest although the clinical diagnosis has occasionally been made Landis believes that some of the cases diagnosed as acute miliary tuberculosis but which recover are instances of this disease and refers to one such patient of his who was alive and well after four years It is characterized anatomically by an ingrowth of connective tissue from the walls of the terminal bronchi with partial or complete occlusion of their lumina

The condition has followed the inhalation of poisonous fumes such as those of nitrogen tetroxide of lime and of chlorine it has developed secondarily to measles, whooping cough pneumonia and syphilis and to the aspiration of foreign bodies It would seem therefore that any inflammatory lesion of the finer bronchi may produce the occlusion

Pathologically in addition to the lesions incident to the primary condition there are numerous small grayish white nodules from 1 to 2 mm in diameter which resemble miliary tubercles but which may be differentiated with a magnifying lens by their angular form and on dissection by their location at the termination of bronchi Microscopically the small bronchioles are found partly or wholly obliterated by the connective tissue ingrowth Adjacent alveoli may be involved in the connective tissue process

The outstanding symptoms are intense dyspnea and cyanosis These disturbances are usually associated with the findings of diffuse fine crackling rales and some hyperresonance When such symptoms and signs follow the temporary subsidence of a bronchitis incident to the inhalation of poisonous fumes the diagnosis should be suspected It is usually missed when the condition is secondary to the inflammatory bronchial lesions of such diseases as measles and whooping cough Bronchopneumonia or acute miliary tuberculosis may come on in a similar manner and be impossible of differentiation The roentgenologic picture of the chest may simulate that of acute miliary tuberculosis

The *prognosis* in obliterative bronchitis is grave but recovery is possible

The *treatment* is symptomatic

Spirochetal Bronchitis—This special form of bronchitis is distinguished clinically from the other types by the presence in the sputum of large numbers of the so called fusospirochetal organisms' spirochetes and fusiform bacilli Other bacterial forms such as the vibrios and cocci may be associated but the fusospirochetes are believed to be chiefly responsible for the inflammatory lesion Not infrequently lung tissue is in

attacks The only characteristic observation is that of the expelled casts Landis refers to a curious flapping sound beginning in the middle of inspiration and extending to its end due to partially separated casts which may occasionally be recognized At times the respiratory murmur in the affected portion of the lung may be absent a case complicated by massive atelectasis has been described by Perlstein

Diagnosis—As already indicated the diagnosis must rest on the finding of the branching casts which can be accomplished most satisfactorily by floating the sputum in water It may be suspected when recurrent attacks of bronchitis with severe paroxysms of coughing and dyspnea occur Such attacks with abnormal physical signs limited to one base should always arouse suspicion of some condition other than simple bronchitis A foreign body or a tumor in the lung may give similar physical signs but in *these the cough and dyspnea are more persistent* and tend to grow worse steadily X ray and bronchoscopic examinations may be necessary to make the differentiation In asthma the signs are more diffuse and the dyspnea is expiratory

Prognosis—In the acute type recovery is usual although an occasional fatality from suffocation due to lodgment of a cast in the larynx has been reported The chronic form is less serious but recurrences take place even after intervals of years and emphysema may eventually result

Treatment—Potassium iodide in large doses is generally recommended Inhalations of creosote and intratracheal injections of medicated oils are sometimes used During the acute paroxysms it is wise to confine the patient to bed in a well ventilated room Circulatory stimulants such as camphor and caffeine are often indicated If suffocation is imminent bronchoscopy or tracheotomy may be life saving

T GRIER MILLER

BRONCHIECTASIS

Definition—Bronchiectasis is a chronic progressive disease of the bronchi or bronchioles characterized pathologically by dilatations of the tubes and an inflammatory reaction in their walls and clinically by chronic cough and the expectoration of large quantities of purulent sputum The dilatations may be congenital or acquired if congenital they are rarely if ever recognized clinically unless secondary infection occurs when the two types give rise to the same symptoms and signs Formerly regarded as rare bronchiectasis is now considered second only to tuberculosis among the chronic affections of the lung

Etiology—The congenital origin of bronchiectasis is supported by its similarity to perhaps identity with congenital cystic disease of the lung by its occasional association with other congenital anomalies (Kartagener) and by the frequency of atelectasis in infants In general however it may be said that two important factors operate to produce the disease first damage of the bronchial wall and second a mechanical influence The latter may act as a distending *force from within the bronchus or as traction* on the wall from without

The most frequent cause of damage to the bronchial wall is infection in the form of a *bronchitis* Long standing sinus disease especially maxillary sinusitis often precedes and is responsible for the bronchial infection The infectious material may be aspirated directly from the nasal cavities into the bronchi or transferred through the lymphatics or blood stream to the peribronchial glands and secondarily to the bronchial walls Other causes of bronchial infection leading to bronchiectasis are the infectious diseases of childhood especially whooping cough and measles Morse believes that in children an interstitial pneumonia is the most frequent cause Influenza by producing an acute widespread peribronchiolar inflammation is an important etiologic agent Other causes of bronchial damage are the inhalation of irritating fumes with resultant sloughing of the bronchial mucosa and softening of the underlying structures the inhalation of inorganic particles such as coal and silicious dusts and the aspiration of foreign bodies

In spite of such damage a bronchial wall will rarely dilate abnormally unless it is subjected to unusual pressure from within or traction from without Relative increase in intrabronchial pressure sufficient to act a

roentgenologic evidence in early cases without fibrosis begin to disappear after the first dose and often recovery takes place after four or five injections Although anatomic cure cannot be obtained in advanced cases with extensive destruction of the lung arsphenamine will often arrest the process and thereby allay the symptoms of activity

Fibrinous Bronchitis —Fibrinous bronchitis also referred to as plastic croupous or pseudomembranous bronchitis is a rare disease characterized by the expulsion of casts which tend to assume the shape of bronchial tubes

Etiology—The cause of fibrinous bronchitis is not known Walker looks upon it as closely allied to bronchitis bronchiectasis and asthmatic bronchitis and states that often there is a previous history of some infectious disease or of a chronic bronchitis Engel believes that a local metabolic disturbance in the bronchi is responsible and compares it to the production of mucous casts in membranous colitis Some claim that a special precipitating ferment mucinase is secreted and can be identified in the serum of patients suffering from the disease Similar casts sometimes occur in laryngeal diphtheria obviously due to the diphtheria bacillus but it is customary to classify these separately In lobar pneumonia tuberculosis measles and scarlet fever also in certain heart affections bronchial casts occasionally develop but these being purely symptomatic are excluded from the so called idiopathic type of fibrinous bronchitis

Morbid Anatomy—Fibrinous bronchitis seems to begin as a simple bronchitis with tenacious fibrinous or mucoid secretion which eventually leads to the formation of casts that fill the bronchi and bronchioles Usually only portions of the lower lobes of the lungs are involved and sometimes but one side of the chest The medium sized tubes are involved first with extension into the bronchioles The bronchial mucosa in the affected areas may show desquamation of its epithelium ulceration or even caseous infiltration The casts themselves are gray white or pinkish in color fairly firm and often several inches in length When expelled from the bronchi they can be floated in water The branches correspond to the divisions of the bronchial tree The larger ones are often hollow and have a laminated appearance due to successive fibrinous or mucous deposits, the smaller ones are solid and terminate in spirals At times they are composed entirely of fibrin again of mucus and still again of the two combined in varying proportions Some blood streaking may be present

Symptoms—Acute and chronic forms of the disease are recognized The *acute form* may begin with a chill fever pain in the chest cough and dyspnea or it may come on with the symptoms of an acute bronchitis Commonly a moderate leukocytosis occurs and some cases show an eosinophilia As the casts form the cough becomes tight and paroxysmal loosening up as the casts are expelled Likewise with the formation of the casts and until they are coughed up an oppressive suffocative type of breathing is present Such cases are usually diagnosed only when the casts are found sometimes by the patient sometimes accidentally by the physician on examination of the sputum They may appear alone or as a pellet surrounded by sputum With them in the sputum may be found Charcot Leyden crystals or Curschmann spirals and eosinophils thus suggesting a condition similar to bronchial asthma The attacks may continue for a few days to several weeks and end in recovery or occasionally in the more severe cases death may result from suffocation

The *chronic form* may develop from an acute attack and commonly manifests itself by recurrent mild paroxysms of the acute type over periods of years The intervals of freedom may be of fixed duration as when the attacks occur at the onset of menstruation or they may be totally irregular and quite long Often in an individual case the casts are of constant size and come from the same bronchial area The clinical picture in the paroxysmal attacks is the same as for the acute variety except that fever rarely occurs The general nutritional state of the patient is not usually affected Emphysema may result and sometimes epistaxis and hemoptysis occur

Physical Examination—The physical signs may be those of an acute or chronic bronchitis or they may be normal Dyspnea and cyanosis may be present in the acute

Desquamation of the epithelial cells frequently occurs early exposing vessels from which hemorrhage may ocur The cilia of the lining cells are usually lost permitting stagnation of fluid and the accumulation of a purulent secretion in the cavities In certain cases known as dry bronchiectasis this secretion is minimal Cultures from material contained within the cavities show a wide variety of organisms

The bronchiectatic cavity may be differentiated from one due to tuberculosis by its smooth walls and by the points of entrance and exit of the involved bronchial tube, furthermore the contained secretion is more often fetid

The surrounding lung tissue may be involved in the morbid process if there is ulceration and destruction of the bronchial wall and fibrosis abscess or gangrene of the lung may ensue When fibrosis is extensive compensatory displacement of the lung and mediastinal structures toward the affected side may be present as well as scattered areas of compensatory emphysema The heart may present evidence of damage as a result of the increased resistance to the pulmonary circulation Pericarditis suppurative pleuritis pneumonia amyloid disease and even intracranial abscess may occur as terminal complications

Symptoms—Early in the disease the symptoms are not distinctive and are often attributed to associated conditions Cough is the chief early symptom and it usually follows an acute respiratory infection The cough may disappear to return however each time the patient contracts a cold or other mild respiratory infection Frequently the only other symptom present at this time is a sensation of lassitude As the disease progresses the cough becomes chronic In a well established case it is characteristically paroxysmal and is brought on by changes in the patient s posture For this reason it is usually most severe in the morning upon arising and at night upon lying down The cough leads in a typical case to the expectoration of large quantities of frothy sputum but the amount may vary from a few cubic centimeters to a liter a day Changes in posture of the patient may greatly influence the amount of sputum and the ease with which it is brought up It is sometimes foul smelling but this feature is by no means as common as was formerly believed Characteristically it settles on standing into three layers an upper frothy layer an intermediate one of thin turbid greenish fluid and a lower heavy one composed of pus cellular debris bacteria fatty acids and hematoidin crystals Hemoptysis occurs in about 50 per cent of the cases and is often copious Recurring respiratory infection of all types is the rule In spite of the chronic cough the patient maintains an appearance of fair health is usually afebrile and does not lose weight until the disease becomes extensive and involves a large proportion of the lung parenchyma Fever and chills may occur with the involvement of new areas of lung tissue and finally late in the disease when a large part of the lung is involved dyspnea cyanosis and pain develop Hemorrhage may occur and in the dry hemorrhagic type it may be the only symptom When the disease begins in childhood the manifestations are somewhat different No sputum is expectorated because of the habit of swallowing it A slight rise in temperature is frequent and because of recurring respiratory infection the child fails to gain weight as he should

Physical Signs—In the early stages of bronchiectasis the physical signs are often obscured by those of the associated bronchial or pulmonary disease chronic bronchitis atelectasis pneumonia emphysema or diffuse pulmonary fibrosis This is especially true when bronchiectasis coexists with tuberculosis In some early cases the physical examination of the chest is entirely negative in others the only positive sign may be the presence of a few rales over a small area usually at the base of one lung On the whole the quality of the physical signs is less important diagnostically than their location Many errors in diagnosis will be avoided if it is remembered how seldom an early tuberculous lesion is found in the lower lobes and how frequently bronchiectasis begins in these areas

As the process develops the signs change and may be very confusing If it is unilateral the breath sounds are usually suppressed and some lagging of the affected side of the chest during inspiration may be observed The mediastinal structures are frequently

a dilating force occurs in various conditions Hedblom has shown that normally with each deep inspiration a difference of about 10 to 20 cm of water exists between the negative intrapleural pressure and the positive atmospheric pressure in the bronchi this constituting the normal distending force within the bronchi Such a force is not sufficient to distend unduly a normal bronchus but it may be sufficient to cause dilatation of one previously injured by infection Any factor, however, which increases the normal disparity between intrabronchial and intrapleural pressure will tend to dilate the bronchi abnormally Such a condition exists when pulmonary atelectasis occurs Because the collapsed lung is unable to expand with the chest wall an increase in the intrapleural space and therefore, an increase in the negative intrapleural pressure occurs This results in an increased difference between the intrapleural pressure and the intrabronchial atmospheric pressure In some cases this difference is said to equal 45 cm of water *Atelectasis* therefore is one of the important causes of bronchiectasis some of the most marked cases of bronchiectasis are seen as a result of this condition Atelectasis itself is most often due to bronchial obstruction and in consequence bronchial obstruction is regarded as the chief cause of bronchiectasis Within twenty four hours after bronchial obstruction atelectasis of the corresponding lung may occur, and bronchial dilatations may be present within a few weeks The lodgment of a foreign body in a bronchus cicatricial stenosis or extramural pressure may be responsible for bronchial obstruction and thus be the ultimate cause of bronchiectasis Fibroid tuberculosis pneumoconiosis unresolved lobar pneumonia repeated bronchopneumonia and lung abscess also tend to reduce lung volume and so bring about bronchiectasis by the same mechanism as atelectasis Bronchiectasis itself produces fibrosis of the adjacent lung tissue and once established tends to perpetuate itself

Cough was at one time thought to be a cause of increased intrabronchial pressure and therefore important in producing bronchiectasis It is true that while the glottis is closed during cough there is some elevation of pressure within the bronchi At this same instant, however sufficient external pressure is exerted throughout the chest by the chest wall and abdominal muscles to counterbalance this increase Cough therefore, unless a bronchus is obstructed is probably not important mechanically in producing bronchiectasis If however, an obstruction is present, cough may increase the intrabronchial pressure beyond the obstructed area Cough also may be important in the etiology of bronchiectasis because it spreads infective material from one bronchus to another this has been observed under the fluoroscope after the instillation of iodized oil

Traction from without the bronchial wall is the other mechanical force operative in some cases of bronchiectasis It occurs in such a condition as adhesive pleurisy, in which during each inspiration this force is exerted Likewise, fibrosis within the lung sometimes so distorts the lung structure that a direct pull is put upon certain bronchial walls during inspiration Under such circumstances the bronchial wall if weakened by infection may yield by dilatation In abscess of the lung also, the factor of traction may be present

Occasionally bronchiectasis is observed without any sign or history of other respiratory infection It is believed that in such instances there may be a primary infection in the bronchus which produces bronchiectasis The sputum in such cases is green unusually foul smelling and shows large numbers of fusospirochetes which are believed to be the etiologic agents

Morbid Anatomy—The bronchial dilatations may be cylindrical saccular or fusiform and vary in size from a few millimeters to several centimeters in diameters They involve either the bronchi or bronchioles or both The upper lobes are rarely the seat of these lesions except when tuberculosis is the cause of the disease The most frequent sites of early involvement are in the lower lobes in the vicinity of the costophrenic and cardiophrenic angles In at least half of the cases the lesions are unilateral The pathologic changes in the bronchial wall depend upon the stage of the disease and vary from almost none in very mild cases to complete destruction of the entire wall with replacement by fibrous tissue in severe cases

come in most cases Churchill in a series of 122 carefully selected cases—some bilateral—had a mortality of only 3 3 per cent, Edwards in 166 lobectomies of only 3 7 per cent (none in fifty four consecutive cases) Johnson has had no deaths in six total pneumonectomies and six lobectomies

Treatment —Prophylaxis is most important This resolves itself into the proper care of all patients suffering from acute or chronic upper respiratory tract infection especially sinusitis the prompt and thorough treatment of all fusospirochetal affections of the mouth careful measures to rid the nose tion no matter what the cause and to manage properly all other recognized pulmonary diseases such as chronic bronchitis lung abscess pneumoconiosis asthma etc At the same time measures designed to improve the patient s general condition are strongly indicated Rest sufficient sleep fresh air and good nutritious food are essential

Special therapeutic measures include the use of antiseptic nasal sprays and mouth washes to prevent irritation and secondary infection from the septic discharges and various procedures to increase drainage from the bronchial cavities Posture may be of

throat and mouth of infection before general anesthesia and the use of all known precautions against the aspiration of foreign material during operations and the prompt removal by the bronchoscope of foreign bodies in the trachea or bronchi Similarly the proper treatment of all bronchial and pulmonary infections must be regarded as a prophylactic measure against bronchiectasis When once the diagnosis of bronchiectasis is made the first obligation of the physician is to treat adequately the suspected causative factors to eradicate foci of infection in the upper respiratory tract and mouth to overcome demonstrated bronchial obstruc the greatest aid in evacuating the bronchiectatic cavities and involves keeping the head and shoulders well below the level of the pelvis for periods of a half hour several times daily This may be accomplished by hanging the head over the edge of the bed until it touches the floor bending the body sharply over a chair or markedly elevating the foot of the bed while using no pillows The inhalation of benzoin or creosote vapor is frequently quite soothing to the irritated throat and bronchial membranes Arsphenamine intravenously is of undoubted value in the cases due to spirochetal infection

The sulfonamides are helpful in many

displaced toward the affected side When the disease is bilateral the signs are often confused with those of a preexisting bronchitis If the lesions are superficially located some hyperresonance or even tympany may be demonstrable on percussion but if deep-seated even fair sized cavities may fail to influence the percussion note Sometimes an area that is dull to percussion may become hyperresonant immediately after a paroxysm of coughing which empties the cavity The distinctive signs of cavity formation—cavernous breathing bronchophony and pectoriloquy—are unusual but may be marked At times a peculiar soft sound suggesting the entrance of air into a small cavity may be heard at the end of inspiration this is known as Skoda s veiled puff

Clubbing of the fingers and toes is more marked in bronchiectasis than in any other pulmonary disease and is consequently of decided diagnostic value These phalangeal changes are particularly common when the lower lobes of the lungs are involved and when suppuration is extensive

In children the physical examination according to Landis is usually negative and the diagnosis depends almost entirely upon the roentgenologic picture

Diagnosis —Early in the disease both symptoms and physical findings are inconclusive and so recourse to special diagnostic procedure is indicated whenever any suspicion of bronchiectasis is aroused Even late in the disease when the symptoms are entirely characteristic the exact location of the lesions is often impossible without the aid of special examinations The first of these is a roentgenologic study of the chest Not always however can the diagnosis of bronchiectasis be made positively from simple x ray investigation The only positive observations from such a study may be some exaggeration of the linear markings of the lungs and when the lung tissue itself is involved a few scattered areas of density in the pulmonary areas These changes while consistent with a diagnosis of bronchiectasis may be simulated by a diffuse bronchitis or by tuberculosis Such study does serve however to eliminate certain other pulmonary conditions and often justifies further investigation regarding bronchiectasis

To arrive at a conclusive diagnosis and to locate the bronchiectatic lesions accurately some opaque medium must be introduced into the bronchial tree The material most widely used for this purpose is iodized oil Its value is greatest when a bronchoscope is used first to remove secretion from the portion of the lung into which the lipiodol is to be introduced Then by means of a catheter previously inserted, the lipiodol should be injected while the patient is under a fluoroscope It can be seen to enter and fill out any bronchiectatic cavities present thus definitely localizing them and establishing the diagnosis It is safer not to use iodized oil when the vital capacity is reduced to 50 per cent, or in the presence of an active tuberculosis hyperthyroidism or iodine hypersensitiveness Bronchoscopy is also an important aid in the diagnosis and should be performed in certain cases in order to eliminate as the cause of disease a foreign body or some other bronchial obstruction Marked clubbing of the fingers is an important diagnostic sign

Smears of the sputum should be examined to eliminate the presence of tubercle bacilli and more rarely the sulfur granules of actinomycosis Special search should be made for the presence of fusospirochetes, since their presence in large numbers indicates a special type of therapy

Because bronchiectasis rarely occurs without other pathology in the bronchi and lungs the chief problem in differential diagnosis is to distinguish between such diseases as chronic bronchitis pulmonary tuberculosis lung abscess unresolved pneumonia and asthma accompanied by bronchiectasis and those same diseases without bronchiectasis This must depend chiefly upon the special diagnostic procedures just mentioned

Prognosis —Bronchiectasis is a progressive disease but if treated effectively in the early stages the chances of complete recovery are fair Later however the process becomes irreversible and unless the involved area is excised leads to chronic invalidism or death from some of the complications Perry and King found that 26 per cent of a non operated series died within five years and that only 0 4 per cent of those who developed the disease in the first decade of life lived to forty On the other hand modern surgical interference offers a favorable out

chills sweats and loss of weight, indicative of chronic pulmonary infection When the foreign body is obstructive to a bronchus the symptoms soon become those of atelectasis or pulmonary abscess

Physical Signs —Jackson has described three pathognomonic signs to indicate the presence of a foreign body in the trachea (1) the audible slap caused by the sudden arrest of the foreign body as it is coughed up against the subglottic narrowing (2) the palpatory thud the sensation transmitted by this arrest to the examiner s finger as it is held over the cricoid cartilage or trachea and (3) the asthmatoid wheeze heard by placing the bell of a stethoscope at the patient s open mouth

With the presence of a nonobstructive foreign body in a bronchus there may be no abnormal physical signs sometimes harshness of breath sounds with an expiratory wheeze and coarse bubbling rales indicative of a localized bronchitis may be audible over the affected area If the obstruction is complete atelectasis with diminished chest expansion on the affected side results and an impairment of resonance with decreased or absent breath sounds may be recognized some displacement of the heart and mediastinal structures to the affected side may be demonstrated At times the foreign body acts as a ball valve allowing the entrance but not the free exit of air under such circumstances a localized emphysema results with displacement of the heart to the opposite side Eventually the signs of pulmonary abscess including clubbed finger ends and curved nails as well as foul and bloody sputum may develop Confusion is not infrequently caused by the presence of auscultatory signs on the nonaffected side these may be due to actual extension of the inflammation or to the shifting of secretions or of the foreign body itself to the other side

Fig 85

Fig 86

Fig 85—Foreign body (peanut) in the left main bronchus producing massive atelectasis and drowned lung In the inspiratory phase the mediastinum is displaced toward the affected side (Courtesy of Dr E P Pendergrass)

Fig 86—Same case as Figure 85 In expiration the mediastinum tends to return to its normal position (Courtesy of Dr E P Pendergrass)

Diagnosis —Radiologic examination is of particular value and often establishes the diagnosis It may demonstrate directly not only metallic foreign bodies but also those of less density such as teeth bones or buttons It may present evidence of bronchial obstruction and so indirectly suggest the diagnosis When the foreign body is acting as a ball valve allowing the entrance but not the exit of air the fluoroscope shows some flattening and limitation of excursion of the diaphragm on the invaded side and at the end of expiration some lessened den

cases and autogenous vaccines should be given a trial Bronchoscopic aspirations are often of the greatest value especially in the preparation of the patient for operation

Since however the process once well developed is irreversible the only hope of cure lies in the surgical removal of the affected portion of the lung Before this is undertaken a complete bronchogram is essential in order to determine the location and extent of the lesion In those cases in which only one lobe or indeed one lung is involved and no infection outside the bronchiectatic area is present particularly if the subject is under forty years of age a lobectomy or pneumonectomy is clearly indicated

T Greer Miller

FOREIGN BODIES IN THE BRONCHI

The presence of a foreign body in the bronchial tree may give rise to obstructive phenomena may lead to extensive bronchial disease or may be the important etiologic factor in the development of such serious lung diseases as bronchiectasis or abscess The resultant pathology and symptomatology depend as Tucker has stated upon the size shape and character of the foreign body its length of sojourn the size and age of the host and the relative area of lung involved Instant death may result from suffocation by a large foreign body in the trachea or no symptoms may be produced for months by the aspiration of a small nonobstructive metallic foreign body

Etiology—Children are especially susceptible to the aspiration of foreign bodies though adults are by no means immune Eighty per cent occur in persons under fifteen years of age Carelessness in putting inedible objects into the mouth and hasty eating are the common causes Carelessness in the extraction of teeth or the failure to remove false dentures before anesthesia is sometimes responsible

Morbid Anatomy—The reaction of the bronchial and pulmonary tissue to the presence of a foreign body depends on the character of the body and the degree of bronchial obstruction Metallic substances if nonobstructive may cause no pathology for months Vegetable materials on the other hand such as peanut kernel, bean or watermelon seed whether obstructive or not, frequently give rise promptly to a violent generalized bronchitis and eventually in children, unless the foreign substance is removed to bronchopneumonia If a bronchus is completely closed the corresponding lung collapses or as more often happens becomes filled with secretions and edematous fluid, a condition which Jackson refers to as drowned lung' If the obstruction is only partial and air can pass on inspiration but not on expiration an obstructive emphysema results In other instances the obstruction to both inspiration and expiration is incomplete varying amounts of air enter and secretions accumulate in the lung from time to time Bronchiectasis and lung abscess often result The foreign body enters the right bronchus in 80 per cent of the cases

Symptoms—No symptoms may be noted at the time of the aspiration though usually an attack of choking gagging coughing and wheezing occurs The cause of such an attack is often not suspected especially if a considerable period without symptoms follows the initial reaction If the foreign body however remains in the trachea the cough persists with hoarseness dyspnea and wheezing until the foreign body is coughed up or passes into one of the bronchi Once in a bronchus there may be no symptoms for a period of weeks or months but cough with expectoration eventually develops and the sputum not infrequently becomes blood streaked If the foreign body is of vegetable origin and in a child the symptoms of a violent diffuse bronchitis so called arachidic bronchitis come on promptly with high irregular fever rapid pulse and respiration a distressing cough cyanosis leukocytosis and the other evidences of a grave toxemia A similar severe reaction according to Heatly and Clausen can be produced in rabbits by the injection into the trachea of the fatty acids from peanuts In adults the immediate reaction to such a vegetable foreign body is purely local but later drowned lung' and pulmonary abscess may develop Even the nonobstructive metallic and nonvegetable foreign bodies eventually produce changes that lead to cough expectoration fever

DISEASES OF THE LUNGS

CIRCULATORY DISTURBANCES IN THE LUNG

ENGORGEMENT of blood in the vessels of the lung occurs far more often than has been supposed It is often mistakenly attributed to heart failure but according to newer knowledge congestion of blood in the lung follows or accompanies many other conditions as well The nature of the vast meshwork of loosely supported thin walled capillaries which forms most of the lung parenchyma and contains about 20 per cent of the circulating blood accounts for the ease with which circulatory disturbances occur and can be detected clinically and at necropsy Furthermore the minute ramifications of vasomotor sensory motor and sympathetic nerves extending even to the alveoli suggest the existence of a delicate nervous control which may be easily disturbed by various stimuli

CONGESTION

Two general forms of pulmonary congestion are recognized active and passive

Active Congestion —Active congestion or simple hyperemia of the lungs is a common occurrence especially in its mildest form It accompanies or follows a multitude of general conditions such as strenuous physical exertion, shock infection and fever inhalation of foreign bodies liquids and hot or irritating gas intoxications trauma allergy and vascular and hemorrhagic diseases In the majority of cases the vascular engorgement is mild unimportant and passes unnoticed The chief danger of active congestion lies in the more severe forms when the transudation of fluid fills the alveoli and interferes with the self cleansing process As a result bacteria which gain entrance or happen to be present may find conditions suitable for growth and infection begins It is probable that most cases of pneumonia and other infections of the lung begin in this manner

In the more severe forms of congestion the circulation in the involved area is slowed fluid escapes and floods varying amounts of lung resorption is interfered with and edema of the lungs develops as described on page 831 In the most intense forms of engorgement which may follow shock inhalation of fluids or gases and severe poisoning death may occur in a few hours

Symptoms —The mildest form gives no symptoms or signs When a large enough area of the lung is involved the onset of pulmonary congestion is indicated by the addition of dyspnea and cough to the symptoms of the primary condition When the congestion is intense pulmonary edema occurs with frothy and often blood stained sputum Rales and suppressed breath sounds may be present especially in the dependent portions of the lungs and an increase in the density of the vascular markings may be seen roentgenographically Slight fever may be present even in the absence of apparent infection If infection does occur the signs symptoms and other evidence of atypical pneumonia appear It is often impossible to decide clinically if infection is present or not

Treatment —Treatment of mild pulmonary congestion as such is seldom necessary Correction of the underlying cause must of course be attempted When the engorgement is caused by hypertension and plethora venesection of 250 to 500 cc (8–16 ounces) of blood may cause striking improvement Rest in bed limited fluid and purgation are helpful Treatment of the severe form is described on page 832 (Pulmonary Edema)

Chronic Passive Congestion —The continuous engorgement of the capillaries in the lung is known as chronic passive congestion There are several causes (*a*) mechanical due to some impediment to the drainage of blood as found in certain heart and lung diseases or (*b*) it may be hypostatic in character

Chronic passive congestion may result from any obstruction to the free flow of blood from the lungs to the heart The causes therefore lie in cardiac vascular pulmonary or extrapulmonary disease Among the cardiac diseases of which this is a prominent feature are mitral stenosis or insufficiency congenital defects and myocardial weakness The latter condition may of course be caused by numerous diseases There is a belief that in such cardiac diseases the chronic pulmonary congestion is by no means as mechanical in origin as is usually supposed but represents rather a

sity of the lung on the same side and some displacement of the heart and mediastinal structures toward the uninvolved side On the other hand when the obstruction is complete and atelectasis is present the uninvolved side of the chest shows less density under the fluoroscope and the mediastinal structures are displaced toward the affected side In any event bronchoscopic investigation is indicated for final verification of the diagnosis

The differentiation from diphtheria pneumonia and influenza must be made in the the cases and in many of these only when the patient is moribund The prognosis when the foreign body is not removed is grave On the other hand bronchoscopy as developed by Jackson and his co workers is relatively safe and has led to cure of the pathologic lung changes in 98 per cent of their cases Even in the cases complicated by abscess or bronchiectasis they report a cure in 94 4 per cent When such conditions as cardiac decompensation acidosis dehydration or empyema exist they must be relieved by proper medical or surgical treatment be-

Fig 87

Fig 88

Fig 87—Foreign body in right lung producing emphysema The right lung field shows evidence of hyperventilation The mediastinum is shifted slightly to the left the right dome of the diaphragm is flattened and the intercostal spaces on the right side are widened (Courtesy of Dr E P Pendergrass)

Fig 88—Same case as Figure 87 The expiratory phase shows normal aeration in the left lung field The right lung is still hyperventilated The mediastinal structures show a greater displacement to the normal side (Courtesy of Dr E P Pendergrass)

acute cases and this can usually be accomplished by a careful history and the physical signs though occasionally roentgenologic and even bronchoscopic study may be required Tuberculosis can be distinguished from the more chronic cases by the location of the physical signs the finding of tubercle bacilli in the sputum and radiologic examination It must be remembered however that tuberculosis and a foreign body may coexist

Treatment—The therapeutic indication in all cases is peroral bronchoscopy for removal of the foreign body Such bodies are expelled by coughing in only 2 per cent of fore bronchoscopy is undertaken Under such circumstances Tucker regards the risk of the procedure as trivial

DISEASES OF THE LUNGS

CIRCULATORY DISTURBANCES IN THE LUNG

Engorgement of blood in the vessels of the lung occurs far more often than has been supposed It is often mistakenly attributed to heart failure but according to newer knowledge congestion of blood in the lung follows or accompanies many other conditions as well The nature of the vast meshwork of loosely supported thin walled capillaries which forms most of the lung parenchyma and contains about 20 per cent of the circulating blood accounts for the ease with which circulatory disturbances occur and can be detected clinically and at necropsy Furthermore the minute ramifications of vasomotor sensory motor and *sympathetic nerves extending even to the* alveoli suggest the existence of a delicate nervous control which may be easily disturbed by various stimuli

CONGESTION

Two general forms of pulmonary congestion are recognized active and passive

Active Congestion —Active congestion or simple hyperemia of the lungs is a common *occurrence especially in its mildest form* It accompanies or follows a multitude of general conditions such as strenuous physical exertion shock infection and fever inhalation of foreign bodies liquids and hot or irritating *gas intoxications trauma* allergy and vascular and hemorrhagic diseases In the majority of cases the vascular engorgement is mild unimportant and passes unnoticed The chief danger of active congestion lies in the more severe forms when the transudation of fluid fills the alveoli and interferes with the self cleansing process As a result bacteria which gain entrance or happen to be present may find conditions suitable for growth and infection begins It is probable that most cases of pneumonia and other infections of the lung begin in this manner

In the more severe forms of congestion the circulation in the involved area is slowed fluid escapes and floods varying amounts of lung resorption is interfered with and edema of the lungs develops as described on page 831 In the most intense forms of engorgement which may follow shock inhalation of fluids or gases and severe poisoning death may occur in a few hours

Symptoms—The mildest form gives no symptoms or signs When a large enough area of the lung is involved the onset of pulmonary congestion is indicated by the addition of dyspnea and cough to the symptoms of the primary condition When the congestion is intense pulmonary edema occurs with frothy and often blood stained sputum Rales and suppressed breath sounds may be present especially in the dependent portions of the lungs and an increase in the density of the vascular markings may be seen roentgenographically Slight fever may be present even in the absence of apparent infection If infection does occur the signs symptoms and other evidence of atypical pneumonia appear It is often impossible to decide clinically if infection is present or not

Treatment—Treatment of mild pulmonary congestion as such is seldom necessary Correction of the underlying cause must of course be attempted When the engorgement is caused by hypertension and plethora venesection of 250 to 500 cc (8–16 ounces) of blood may cause striking improvement *Rest in bed limited fluid and purgation are* helpful Treatment of the severe form is described on page 832 (Pulmonary Edema)

Chronic Passive Congestion —The continuous engorgement of the capillaries in the *lung is known as chronic passive congestion* There are several causes (*a*) mechanical due to some impediment to the drainage of blood as found in certain heart and lung diseases or (*b*) it may be hypostatic in character

Chronic passive congestion may result from any obstruction to the free flow of blood from the lungs to the heart The causes therefore lie in cardiac vascular pulmonary or extrapulmonary disease Among the cardiac diseases of which this is a prominent feature are mitral stenosis or insufficiency congenital defects and myocardial weakness The latter condition may of course be caused by numerous diseases There is a belief that in such cardiac diseases the chronic pulmonary congestion is by no means as mechanical in origin as is usually supposed but represents rather a

protective mechanism designed to relieve the heart by pooling a considerable volume of blood in the capillary bed of the lungs thus reducing the amount of blood which the heart must keep in circulation at nearly constant speed It may be therefore the physiologic equivalent of hemorrhage or venesection

Chronic passive pulmonary congestion may develop also as the result of obstruction to the pulmonary circulation due to diseases of the lungs as in cases of hypertrophic pulmonary emphysema fibrosis, sclerosis, atelectasis pneumonoconiosis chronic abscesses, bronchiectasis or tumors and in mediastinal tumors which press against or invade the pulmonic veins

Pathology —Lungs the seat of long standing chronic passive congestion, are heavy and have a typical russet brown color (brown induration of the lung) The cut surface, sometimes dry, sometimes edematous has a brownish red hue The capillaries of the alveoli are overdistended with blood their walls show evidence of degeneration and desquamation and the air spaces contain a slight amount of serum red cells and macrophage cells filled with granules of hemosiderin In long standing cases there is marked increase in the interalveolar connective tissue (see Fibrosis p 847)

Symptoms —Chronic passive congestion even when marked in patients with heart disease may give no pulmonary symptoms as long as cardiac compensation is well maintained This is surprising in view of the increased rigidity of the lungs and the marked overfilling of their capillaries During this stage however the patient is susceptible to attacks of bronchitis With developing cardiac decompensation and the resulting slowing up of the pulmonary circulation certain pulmonary symptoms become manifest Among these are dyspnea cough and the expectoration of sputum which may for a long time be uniformly rusty or marked by rusty streaks and dots This color is due to masses of the characteristic heart failure cells which are phagocytic mononuclear cells filled with granules of modified free hemoglobin In such cases the sputum frequently is also definitely blood tinged and small pulmonary hemorrhages occur frequently

This occurrence often leads to a diagnosis of unsuspected stenosis of the mitral valve The portions of the lung involved in the process are common sites for the development of atelectasis or pneumonia

Dulness rales and suppressed breath and voice sounds are usually present over the involved areas Cyanosis and dyspnea are common Abnormal density and increase in the shadows of the vascular markings are found in the roentgenogram Fever may be absent but is often of low grade especially if infection occurs which it commonly does

Hypostatic Passive Pulmonary Congestion —Quite different from the mechanical form of congestion is a condition characterized by stagnation of blood in the dependent portions of the lungs It may develop during *protracted fevers* as typhoid and in those adynamic states which result from unconsciousness long debilitating diseases malnutrition cachexia and senility, particularly when the patient lies for a long time in one position

Hypostatic congestion may develop in the lower lobes long collapsed because of a high position of the diaphragm, as in cases of ascites meteorism or abdominal neoplasms also in cases of brain injury or organic disease of the brain *At necropsy*, the posterior inferior or dependent portions of the lower lobes of the lungs are dark in color and so soggy with blood and serum that the alveoli may no longer contain air Gravitation doubtless determines the localization of hypostatic congestion but this alone is not sufficient since it does not occur in healthy persons and in certain sick ones no matter how long they remain in one position in bed Long continued hypostatic congestion may so lower the resistance of the lung tissue to secondary infections that a low grade chronic pneumonia may develop

Symptoms —The symptoms of hypostatic congestion are not characteristic They include cyanosis respiratory distress and cough with abundant sputum containing heart failure cells On physical examination tactile fremitus is decreased and percussion may reveal slight dulness on auscultation feeble sometimes blowing breath sounds with showers of crackling rales are heard Pneumonia is suggested by a low fever physical signs suggestive of pulmonary con

solidation and shadows in the roentgenogram

Treatment—To forestall the development of hypostatic passive congestion all patients with long standing asthenic or debilitating conditions should be taught to practice deep breathing exercises regularly Deep breathing may be induced by administering with a face mask gas composed of carbon dioxide 5 parts and oxygen 95 parts The application of the mask should be intermittent the time determined by the patient s response and comfort Their position in bed should be changed from time to time and if possible they should be allowed to sit up in a chair The treatment of this condition is that of the condition inducing it and should include all measures that may bring about an improvement in the patient's general condition Attention should be given to improving the patient s morale with psychotherapy physiotherapy and proper diet

HOBART A REIMANN

PULMONARY EDEMA

In pulmonary edema there is a sudden or gradual escape of serous fluid from the capillaries into the lung tissue the alveoli bronchioles and often into the bronchi A part or the whole of one or both lungs may be involved In some cases edema seems to be an extreme stage of acute or chronic congestion and in others to arise from a number of other conditions In most instances edema of the lungs seems to be one factor in a general systemic collapse but it may occur as an isolated incident without other evidence of circulatory failure All grades of severity are encountered from the mildest which is common to the severe fulminating form with early death from suffocation

Etiology—*The Mechanical Group*—Weakness of the left ventricle and back pressure into the blood vessels of the lung was long thought to be the chief cause of pulmonary edema but in a critique of the subject Luisada concludes that this theory is inadequate nor is there direct evidence favoring a purely neurogenic theory The cause is not definitely known and seems to be a combination of factors in most cases When a tendency toward the occurrence of edema of the lungs is present, stasis or an increase in pulmonary blood volume favors its development Increased permeability of the capillary walls brought about by vasomotor reflexes may take place This may explain the edema which occurs in shock angioneurotic edema or epilepsy Pulmonary edema may develop in valvular heart disease pericarditis aortitis angina pectoris coronary thrombosis pulmonary infarction drowning and during nephritis especially in advanced nephrosclerosis arterial hypertension and uremia

The Infectious Group—Acute pulmonary edema may complicate many of the acute infectious diseases In these it may be a terminal event The cause is not clearly understood but is believed by some to be the result of a toxic effect on the centers controlling the vasomotor system of the lungs or following collapse and failure of the circulatory system with pulmonary edema as a result

The Toxic Group—Patients severely poisoned by various substances such as alcohol barbital compounds iodine morphine epinephrine and asphyxiating gases may develop pulmonary edema In these it may be caused by the same neurogenic factors discussed in the infectious group Edema may of course follow the inhalation of numerous irritating gases as commonly used in commercial fields and in warfare The edema and suffocation may occur immediately after exposure or may be delayed for many hours and develop suddenly after a period of relative well being

Other Causes—In women more cases of pulmonary edema develop during pregnancy and confinement than in those with primary cardiac conditions Some have recommended therapeutic abortion in women who become pregnant after surviving a previous attack Pulmonary edema is also noted at times in diseases of the central nervous system such as trauma to the brain myelitis cerebral embolism and thrombosis In rare cases and for unknown reasons it has followed thoracic and abdominal paracentesis Pulmonary edema is common in shock

Pathology—The generally edematous lung is found at necropsy to be *anemic* heavy and sodden It pits on pressure and when incised large quantities of clear or

blood tinged foamy serum flow from it It may in places have a gelatinous aspect

Symptoms—The onset of edema may be gradual or sudden and is manifested by a feeling of oppression or pain in the chest, and rapid breathing with dyspnea or orthopnea There may be an incessant short cough, and a copious frothy sometimes blood tinged fluid gushes from the mouth and nose The face becomes pale and covered with cold sweat, the pulse is feeble and the heart s action weak Over the entire chest piping and bubbling rales may be heard The temperature and blood pressure fall An attack may be fatal in a few hours in other instances symptoms persist for twelve to twenty four hours and then disappear Repeated attacks may occur When fatal the edema usually develops slowly and insidiously with coma and is manifested at first by coarse moist rales throughout the chest which soon obscure all other lung and heart sounds and later become audible even at a distance (the so called death rattle') In the advanced stage streams of foamy fluid slowly pour from the nose and mouth The prognosis is always grave

Treatment—The management varies with the cause A primary condition if not evident should be sought for and appropriately treated When pulmonary edema is threatened the fluid intake should be promptly but temporarily reduced Aromatic spirits of ammonia 4 cc (1 drachm) may be given by mouth In general patients should be treated as for shock Bed rest and maintenance of body warmth is important In plethoric or hypertensive patients venesection of 250 to 500 cc (½–1 pint) of blood often results in striking improvement Amyl nitrite 0 3 cc (3 minims) by inhalation or sodium nitrite 0 06 Gm (1 grain) by mouth are said to be of value This procedure of course is not indicated in shocklike conditions with collapse and hypotension In the latter case sucrose in 100 cc doses of a 50 per cent solution may be injected intravenously This form of treatment unfortunately is seldom helpful because the problem is not especially one of loss of fluids but of failure to keep the fluid in the circulatory system moving Epinephrine hydrochloride 1 cc (15 minims) may be added to the solution or injected subcutaneously in an attempt to restore the blood pressure Atropine is traditionally recommended by some to dry up the secretions' but it is doubtful if it exerts any more effect on edema of the lungs than on edema elsewhere It may actually be harmful by speeding the heart rate Nevertheless many give it hypodermically in large doses 1 2 mg (1/50 grain) and claim success

Morphine sulfate in doses of 15 mg (¼ grain) tends to relieve edema of the lungs by lowering the excitability of the central nervous system It should not be given in states of collapse

Transfusion of blood (250 cc to 500 cc.) may be indicated for anemia and transfusion of plasma (16 to 32 Gm) for hemoconcentration or loss of blood volume unless heart failure is present

Oxygen Therapy—The inhalational treatment of pulmonary edema is in the first place the provision of a high oxygen concentration between 50 and 100 per cent oxygen The specific procedure which has been found valuable is the application of positive pressure between 2 and 5 cm. of water Although the helmet hood apparatus, which provides positive pressure in inspiration and expiration is the most effective method of applying this therapy, a similar method has been successfully employed namely an adaptation of the meter injector mask which consists of a metal disc enclosing the expiratory valve and perforated with variable sized orifices When expiration is conducted through a restricted orifice a positive pressure is developed which is directed backward against the pulmonary epithelium and tends to prevent transudation of serum The positive pressure first employed is 3 or 4 cm of water and is gradually lowered at the rate of 1 cm of water every one to four hours depending upon the clearing of edema and the condition of the individual patient The administration of positive pressure in conjunction with 100 per cent oxygen may be also used in cases of pulmonary edema due to industrial and war gas poisoning In medical or surgical shock, in which there is a deficient return of blood to the heart the increased intrapulmonary pressure may further retard the entrance of blood into the right auricle Positive pressure under these circumstances should be

applied only on expiration and cautiously for short periods at a time only If it is followed by a drop in the systolic blood pressure of more than 10 mm Hg the positive pressure should be lowered or dispensed with However in pulmonary edema as a complication of pneumonia heart disease or increased permeability of the capillaries it is frequently of great value and may be used until the edema clears If there is a return of pulmonary edema positive pressure should again be applied and the attempt made to lower the pressure gradually

Patients who have repeated attacks of pulmonary edema should be warned against overexertion or other activities likely to bring on an attack If pulmonary edema accompanies labor the uterus should be emptied

PULMONARY HEMORRHAGE

Bleeding from the lungs occurs in two forms in one the blood pours into a bronchus or open pulmonary cavity from a ruptured blood vessel and is immediately expectorated as a bright red fluid either pure or mixed with sputum or if temporarily retained as a dark brown or black material often in clots In the other form it passes into the alveoli or interstitial tissues by diapedesis or rupture of capillary walls and is expectorated as blood stained sputum either bright red or more usually brownish from modified hemoglobin The first form is by far the more dangerous The difference between the terms hemoptysis and hemorrhage is in the quantity of blood raised Amounts less than 4 cc (1 drachm) are usually regarded as hemoptysis

Bleeding from the lungs occurs most commonly in pulmonary tuberculosis and bronchiectasis It may be the first sign of either disease In both diseases it results from the erosion of veins or arteries in the ulcerative process The amounts raised in the sputum may be insignificant or large enough to cause early death from hemorrhage especially if an artery is opened Hemorrhage may be a single event or it may be intermittent or continuous for several days In most cases only a portion of the blood is expectorated the remainder is either swallowed or enters the dependent portions of the lung where atelectasis and a low grade inflammatory process may begin which slowly disappears as the blood is absorbed

In a considerable number of cases the cause of pulmonary hemorrhage is never determined In rare cases in women it occurs during the menstrual period and has been considered as vicarious menstruation' Hemorrhage from the lung in the menstrual period is common in tuberculous women and in those with hemorrhagic diseases Hemorrhage may occur in severe hypertension

Bleeding from the lungs may occur in many other pulmonary diseases such as chronic fungous or parasitic infections neoplasms cysts gangrene abscess emphysema atelectasis arteriosclerosis trauma and amyloid disease True hemoptysis is not a feature of pneumococcic pneumonia in which the color of the sputum is due to the gradual seepage of blood into the alveoli Hemoptysis is however a frequent occurrence in Friedlander s bacillus pneumonia in its acute or chronic form The sputum in whooping cough is often bloody Gun shot and stab wounds must be mentioned

Numerous other nonpulmonary diseases are occasionally characterized by hemoptysis Small amounts of blood are frequently raised in mitral stenosis Ulcerations in the larynx trachea and bronchi and rupture of an aneurysm into the respiratory tract may lead to fatal hemorrhage Pressure of an aneurysm or new growth from without or the presence of a foreign body may cause hemoptysis over long periods Widespread and intense capillary congestion with rupture and hemorrhage into the walls of the small bronchioles and alveoli of both lungs occurs in pulmonary concussion as a result of proximity to the detonation of high explosives (page 835)

Scurvy and diseases of the blood such as purpura granulocytopenia hemophilia and leukemia may cause hemoptysis

Symptoms —Severe hemoptysis occurs as a gush of blood bright or dark red in

color which may flow from the mouth almost without coughing Warning may be given by the previous appearance of slight blood stains in the sputum Hemoptysis as a rule appears suddenly, often without warning other than the desire to cough, or the sudden presence in the mouth of a warm salty fluid Slight hemorrhages may be single or may recur for days followed for several more days by blood tinged sputum In contrast to these are the profuse hemorrhages sufficient even to drown the patient, which follow the erosion of a large pulmonary blood vessel or the rupture of an aneurysm

Diagnosis —When hemoptysis occurs the chest should at once be thoroughly examined by auscultation in order to determine if possible from which lung the bleeding comes A history should be immediately obtained from the patient, or from some relative or friend so as to determine the cause of the hemorrhage If feasible a roentgenogram should be made at the bedside with a portable apparatus The movement of the patient to allow this examination is not as dangerous as is usually assumed In cases of repeated hemoptysis of doubtful etiology laryngoscopy or bronchoscopy should be performed by an expert since not only may the bronchus leading to the bleeding area be thus identified but it may be discovered that instead of being a pulmonary lesion the hemorrhage originates from an ulcer in the trachea or large bronchus and the lesion may be so situated that it can be treated locally Appropriate tests should be employed for all diseases listed as possible causes

Blood from the lungs is alkaline and frothy in contrast with that coming from the stomach which is apt to be acid often granular and darker in color Blood from the lung may of course be swallowed and later vomited

Prognosis —Small pulmonary hemorrhages may by relieving pulmonary congestion actually prove beneficial Unless very profuse hemoptysis seldom is immediately dangerous In the great majority of cases it soon ceases spontaneously The immediate dangers of profuse hemorrhage are death by suffocation, spread by the blood of the germs of the underlying infection aspiration pneumonia massive collapse of a lobe or of a lung either from spasm of its bronchus or from its occlusion by a blood clot, and the weakness or shock due to the resulting anemia

Treatment —Any underlying cause if present should be found and eliminated In the majority of cases of hemoptysis either the patient is dead before the treatment can be begun or the bleeding has already stopped spontaneously If in the case of profuse hemorrhage the patient can be kept alive for twenty four hours, the immediate prognosis is good Often the syncope induced by the sudden loss of considerable blood saves life by promoting thrombosis All diet and previous medication should at once be stopped The patient should lie on the affected side in order to protect the sound lung from the free blood in the trachea and bronchi An ice bag placed against the side of the chest has much the same value as a sand bag which by its weight immobilizes the chest The main therapeutic procedures to be recommended are absolute rest in bed, reduction of the blood pressure if it is abnormally high by a minimum diet purging and measures to allay the cough Peace of mind is of great importance but is most difficult to attain because of the frightened state of the patient It should be secured by calmness and reassurance but often a hypodermic injection of morphine 0 01 Gm (1/6 grain) or more is necessary For the cough which is usually present and disturbing opium should be given to lessen but not to suppress it The patient should be instructed not to cough unnecessarily or too hard A moderate amount of cough is desirable to clear the lungs and bronchi of blood The patient may be allowed to suck small pieces of ice In some protracted cases of bleeding artificial pneumothorax has stopped the hemorrhage

Theoretically it would seem desirable to reduce the frequency of the heart beats to lower the general blood pressure and to increase the coagulability of the blood The drugs commonly used however seldom accomplish these purposes indeed some of them raise the peripheral blood pressure and therefore may be harmful This appears to be true of digitalis and of ergot while the nitrites tannic acid and lead are of little or no value On the other hand aconite atro

pine and pituitary extract seem to reduce the pressure in the lesser circulation and, therefore may be helpful One of the most satisfactory means of lowering the general blood pressure in plethoric hypertensive patients is purgation and when the bleeding is protracted saline cathartics should be given in repeated doses Alcohol should never be allowed A transfusion of 100 cc of blood may control the bleeding It is said that intravenous injections two or three times daily of 10 units of parathyroid hormone sometimes succeed after other methods have failed Other measures advocated are the prompt intratracheal injections of adrenalin or better some say of distilled water which produces reflex contraction of the bronchi

For the treatment of severe and repeated hemorrhages the following surgical measures have been advocated phrenic exeresis pneumothorax the division of pleural adhesions extrapleural pressure against the lung thoracoplasty

HOBART A REIMANN

PULMONARY CONCUSSION

(*Lung Blast*)

Diffuse capillary hemorrhage of the lungs resulting from close proximity to the detonation of high explosives occurs in civil life but has become much more frequent with military bombing The majority of cases occur in persons bombed in closed spaces The lesions consist chiefly of bleeding from the alveolar capillaries In severe cases massive hemorrhages and rupture of goblet cells occur with the liberation of much mucus Both lungs are usually affected

Symptoms —All grades of severity occur depending upon the force of the explosion the distance from it the environment and the condition of the patient Death may be instantaneous without outward signs of injury but the majority of cases are less severe and most patients recover There is usually prostration dyspnea tachycardia and oppression or pain in the chest Cough and fever develop later Physical signs vary from those of congestion to consolidation Bulging of the chest is noted Mottled areas of density are seen in roentgenograms As in other forms of shock the onset of symptoms may be delayed for many hours All persons close to an explosion particularly in enclosed spaces should be confined to bed and observed for at least twenty four hours The treatment is the same as that for the general management of shock or of pulmonary hemorrhage (p 834)

Treatment.—Heat oxygen morphine and transfusion of plasma are of greatest value Intravenous injection of fluid should be given with caution to avoid pulmonary edema Incorrect methods of artificial respiration may cause further harm Complications or sequels such as shock or pneumonia should be anticipated Other visceral injuries sustained at the same time must be suspected If an anesthetic for surgical purposes is required it should be given intravenously

PULMONARY INFARCTION—PULMONARY EMBOLISM AND THROMBOSIS

A pulmonary infarct consists of a mass of airless lung tissue infiltrated with blood which has extravasated into the air cells and interstitial pulmonary tissue The condition results from closure by an embolus or thrombus of the pulmonary artery supplying the affected area The lung tissue in the infarct does not as a rule become destroyed unless the collateral circulation is also impaired

An embolus or thrombus large enough to close a main pulmonary artery or one of its largest branches causes widespread pulmonary edema without hemorrhagic consolidation and promptly proves fatal Atelectasis may occur as a result of bronchial constriction caused by a reflex reaction The occlusion of one of the medium sized branches often produces a hemorrhagic infarct but not always Indeed the closure of even moderately large branches of the pulmonary arteries may do no harm unless the lung already is the seat of chronic passive congestion as in some types of heart disease

Incidence—Many emboli which reach

the lung are fragments of mural thrombi so *common in the right auricle* in cases of bacterial endocarditis and auricular fibrillation in which slowing of the blood stream seems to be an important factor Others arise peripherally especially from phlebitis in the legs and from the pelvis in cases of pregnancy puerperal sepsis pelvic inflammatory disease and prostatitis *Pulmonary* vessels may be closed also by thrombus formation with an infarct often the result This occurs in some of the acute infections such as typhoid and in all conditions in *which the blood flow in the lesser circulation* becomes greatly retarded Changes in *the composition of the blood* such as occur in hyperinosis and thrombocytosis and perhaps a decrease of antithrombin and heparin may also play an important role by increasing the tendency to clot

Pulmonary infarction is the immediate *cause of about 2 per cent of all deaths* it is found in nearly 4 per cent of all necropsies on children In surgical practice emboli to the lung explain 50 per cent of all important postoperative complications while 50 per cent of all deaths following pelvic operations are due to pulmonary complications some of them embolic in origin and others atelectatic Any patient with bacterial endocarditis phlebitis auricular fibrillation or with a history of recent surgical operation or severe trauma is in danger of pulmonary embolism The condition is three times as common in obese as in slender persons and is most common between the ages of forty and sixty

Symptoms—The *symptoms of lung infarction*, when typical are a sudden piercing pleural pain which radiates to the shoulder dyspnea sudden in its onset, often with signs of collapse an irritating cough with hemorrhagic sputum or small hemoptyses and occasionally an annoying continuous hiccough The patient looks anxious is cyanotic has *tachycardia* and sweats profusely On physical examination if the *infarct is* large and favorably located there is a local area of impaired resonance a localized friction rub distant bronchial breath sounds and moist rales The patient expectorates round nummular masses composed of more or less thoroughly mixed mucus and blood which remain discrete in the cup Fever or leukocytosis is usually present but may be absent Jaundice is occasionally present In about 15 to 20 per cent of the cases with such signs the patient dies In cases of rapidly fatal pulmonary embolism or *thrombosis the patient feels a sudden pain* or sense of tightness in the chest especially under the sternum He becomes ashen in color anxious and then cyanotic and dyspneic Pulmonary edema develops, the pulse becomes feeble or imperceptible, death follows in from a few minutes to several hours Some infarcts cause characteristic symptoms *but no physical signs* and others the opposite or neither Embolic lung infarction following surgical operations usually develops within the second or third week that following trauma such as a fractured bone during the fourth or fifth week after the injury During the above mentioned periods the temperature usually rises to 99° or 100° F daily—evidence possibly of thrombophlebitis In such cases however the emboli are small and seldom of themselves prove fatal Symptoms of pulmonary *fat embolism* particularly from fractured bones arise several hours or days after the injury

In some instances the circulation becomes reestablished and the extravasated blood is *eventually removed or the infarct ultimately* becomes a pigmented, puckered fibrous scar Secondary infection of the infarct may lead to sloughing abscess or massive necrosis with cavity formation If such an infarct ruptures into the pleural cavity it produces pneumothorax or pyopneumothorax

Pathology—Infarcts vary in size from *that of a pea to that of an orange* and average 3 × 2 × 1 cm in size They are irregular in shape and are almost always in contact with the pleura *Often they are* multiple The majority of them are in the lower lobes

Recent infarcts are dark but those a *little* older are reddish brown in color They are hard and firm and on section look like ordinary blood clots Microscopic examination shows that the air cells and alveolar walls *are distended with red blood corpuscles*

Diagnosis—Small infarcts seldom are correctly diagnosed usually such conditions are interpreted as pleurisy, *pneumonia* atelectasis or coronary occlusion In some cases however the symptoms and physi

cal signs of infarction are quite unmistakable Some infarcts even large ones fail to render the sputum bloody Sometimes hemoptysis is the only sign of infarction and its appearance in cases of heart disease particularly mitral stenosis should always suggest the possibility of this lesion although in the majority of cardiac patients such hemorrhages usually are due to pulmonary congestion Often an infarct gives no physical signs but of those which are obtained a pleural friction rub is the most constant Unexplained fever or jaundice dyspnea cyanosis tachypnea tachycardia hemoptysis and prostration are all important diagnostic clues

Fig 89—Infarcts in the right lower lobe The patient had hypertension and at necropsy three weeks after the roentgenogram was made mural thrombosis of the right auricle and the remains of pulmonary infarcts were found (Courtesy of Dr L. G Rigler)

Roentgenograms though seldom convincing are often suggestive (Fig 89) Infarcts appear as areas of localized haziness or as small irregularly shaped shadows Evidence of atelectasis may be present

Prevention —Attempts should be made to combat or neutralize those factors known to favor the development of infarcts namely slowing the blood stream and an increase of the elements concerned in the clotting of blood Patients should not be completely immobilized as a certain amount of movement favors the maintenance of the speed of circulation Deep breathing exercises are of value Little can be done to alter the composition of the blood except to give heparin and thus render the blood less coagulable To prevent postoperative thrombosis or thrombophlebitis heparin has been given intravenously either intermittently or continuously with reported success (Mason)

Treatment —When infarction occurs the patient should remain quietly in bed Morphine sulfate 15 mg (¼ grain) repeated in fifteen to thirty minutes is the most valuable drug to relieve pain dyspnea and apprehension It should be used even in the presence of cyanosis or collapse If shock develops treatment is the same as described for Pulmonary Edema (p 832) The intravenous injection of papaverine hydrochloride 0 03 Gm (½ grain) and atropine sulfate 0 45 mg (1/150 grain) has been recommended by some to block off vagal effects and relieve spasm of the bronchi and blood vessels The injection may be repeated Oxygen therapy may relieve dyspnea and cyanosis Heparin has been used with success to render the blood less coagulable

PULMONARY ATELECTASIS

(*Simple Atelectasis Massive Pulmonary Atelectasis or Collapse*)

Atelectasis or collapse of the alveoli of the lungs occurs far more commonly than is generally believed Physiologic atelectasis occurs during rest

Simple Atelectasis —A multitude of diseases or conditions of the lung including infections surgical operations shock edema trauma pulmonary embolus and infarct foreign bodies in the lungs or bronchi, irritants extra pulmonary pressure and nervous factors may cause a functional failure of greater or lesser numbers of alveoli This results in partial or complete deflation and immobilization in the deflated state Atelectasis is especially common in influenza and often occurs during tuberculosis and other forms of pneumonia Its presence often confuses the physical findings of the primary disease The existence of collateral respiration recently discovered is no doubt a great factor in preventing serious collapse from occurring more often than it does

There are no signs or symptoms if small areas of lung are involved But if enough pulmonary tissue is affected there may be dyspnea tachypnea cyanosis and tachycardia The physical signs vary greatly They are chiefly those of suppression of breath and voice sounds and rales Dulness is not evident unless large portions of lung near the pleura are collapsed The signs are often transient and migrate from place to place as old areas clear up and new ones form The signs may change considerably when the patient rolls from one side to the other

Treatment is seldom necessary but frequent change of the patient s position and deep breathing exercises may be helpful in preventing the condition or in clearing it up Sedatives and oxygen may be helpful for severe dyspnea Abdominal distention and tight binders should be avoided Circulatory failure if present should be appropriately treated

Massive pulmonary atelectasis implies the sudden and complete collapse of one or more lobes of one or both lungs (Fig 90) The etiology of the condition is unsettled the chief causes are believed to be (*a*) sudden obstruction of the bronchi (*b*) pulmonary infarct (*c*) infection, (*d*) allergy and (*e*) nervous stimuli The majority of cases follow anesthesia and *surgical operations* especially on the abdomen or after some physical injury The occasional presence of plugs of mucus in the bronchi supplying atelectatic lobes suggests their causative role in this condition but mucous plugs may be the result and not the cause of the disturbance Massive collapse also follows acute bronchial obstruction or trauma from any cause asthma pneumonia tumors swollen lymph nodes (Fig 90) pleurisy foreign material (blood water solids) in the lung external pressure nervous shock spontaneous or induced pneumothorax and many other conditions It may be the cause of death in these disorders

The area collapsed usually reexpands rather promptly when the cause is removed Prolonged collapse may result in permanent fibrosis

Pathology —At necropsy in cases of massive collapse the mediastinum and heart are pulled toward the affected side of the thorax, the diaphragm on that side is high and the lung is collapsed firm and so airless that it sinks in water One lobe or an entire lung may be involved the right three times as often as the left There is *compensatory* emphysema of the other lung The condition sometimes is bilateral Evidence of closure of the bronchus is not always found

Symptoms —The fully developed symptom complex of massive pulmonary collapse is unique since it appears in no other condition The symptoms in postoperative cases commence within twenty four to forty-eight hours They may be mild or so severe as to cause sudden death The onset usually is sudden with dyspnea tachypnea cyanosis tachycardia prostration and pain usually in the lower part of the thorax The patient

sits up in bed, is cyanotic and breathes rapidly His facies expresses great anxiety and yet he does not really look sick if he does it is from some associated condition The same is true even if cough and sputum are present The temperature ranges from 100° to 104° F The pulse rate varies from 110 to 130 the respiratory rate from 40 to 50 per minute and the leukocyte count from 10 000 to 20 000 per cubic millimeter

Physical Signs —Of the physical signs of massive collapse the most characteristic or less flat especially posteriorly If the condition affects the right side the flat note over the lower chest is explained in large part by the high position of the liver The voice sounds are absent or diminished according to the degree of collapse and the breath sounds are suppressed but bronchial if the collapse is not complete in which case the breath sounds are inaudible Local rales coarse and often musical in character are heard but only while the collapse is developing or subsiding Distant rales also may be

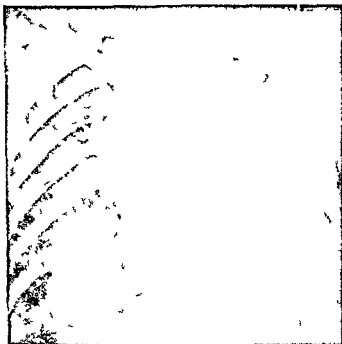

Fig 90—Massive atelectasis of the left lung The patient, aged 22 had Hodgkin s disease of the mediastinal lymph nodes A previously made roentgenogram showed extensive widening of the mediastinum with displacement of the esophagus to the right There were physical signs of emphysema in the left lung and the patient was dyspneic and cyanotic

The roentgenogram above made a week later shows the heart and mediastinum pulled to the left, the left half of the diaphragm elevated and the intercostal spaces narrowed on the left and broadened on the right. The collapse occurred without clinical symptoms but the physical signs consisted of dulness with absent breath and voice sounds over the left lung

are those which indicate that the heart mediastinum and diaphragm are moved toward the affected side and that the other lung is overdistended The chest wall on the affected side looks flat its intercostal spaces may be narrowed or depressed its respiratory movements are diminished or absent and sometimes are reversed those of the normal side are excessive On the affected side the vocal fremitus may be decreased or absent according to the degree of atelectasis the note on percussion is more heard The percussion note over the unaffected side on the other hand is hyperresonant since this lung is emphysematous its margins extend beyond their normal limits The elevation of the diaphragm and dislocation of the mediastinum may persist after all pulmonary symptoms have disappeared

Diagnosis —In the diagnosis of massive collapse of the lung the most important single point is the displacement of the heart toward and the high position of the diaphragm on the affected side This should

be verified by a roentgenogram Other points of great weight are the sudden onset of the illness with cyanosis and increased respiratory rate and the marked discrepancy between the extensive physical signs and the absence of malaise While the diaphragm is high and immobile it is not quite as immobile in spontaneous collapse as in collapse due to foreign body in a bronchus At first one may suspect lobar pneumonia pleurisy with or without fluid pneumothorax pulmonary embolus or thrombosis or diaphragmatic hernia Roentgenograms will show on the affected side a dense shadow which represents the collapsed lung, heart mediastinum, and diaphragm (Fig 90)

Prognosis —The prognosis is usually good the condition disappearing in a week or ten days *unless the primary disorder is permanent* or serious it is bad if the collapse is bilateral or persistent or if pneumonia follows

Treatment —The cause if present should be removed If the collapse is due to bronchial obstruction bronchoscopy may be necessary Small doses of morphine sulfate 0 01 Gm (1/6 grain) may be helpful if the patient is excited or distressed by the dyspnea The patient should be rolled from side to side or should lie with the affected side up to facilitate the drainage of secretion Deep breathing should be encouraged and if it fails a mixture of oxygen 95 per cent and carbon dioxide 5 per cent should be *given by inhalation If atelectasis* is caused by bronchoconstriction resulting from reflex stimulus De Takats recommends the intravenous injection of atropine sulfate 0 45 mg (1/150 grain) and papaverine hydrochloride 0 03 Gm (1/2 grain) to block off vagal effects and to cause vasodilation

Prevention of atelectasis after surgical operations is more important than treatment After operation the patient should not be deeply narcotized and tight binders should not be placed about the chest or upper part of the abdomen The patient s *position* in bed should be occasionally changed and deep breathing encouraged Collections of secretion in the oropharynx *should* be aspirated It is important to keep the patient warm comfortable and reassured

ABSCESS OF THE LUNG

Definition —Abscess of the lung is a localized area of suppuration in the lung with *or without cavitation It is* accompanied by more or less necrosis of tissue which if massive is usually called gangrene

Abscesses may be classified as (*a*) single unilocular or multilocular central or peripheral closed or open to the bronchus or pleura and (*b*) multiple in one or both lungs In one series of 315 cases (Maxwell) examined postmortem instances of single abscess numbered 199 and of multiple abscesses 116 They may also be classified as primary and secondary Many chronic abscesses are surrounded by areas of bronchiectasis

Etiology —The bacterial cause of lung abscess in most cases is confused since a variety of micro organisms is usually present In certain instances however especially early in the disease bacteria such as Friedlander s bacilli staphylococci certain fungi *Endamoeba histolytica* and others may be found alone Streptococci colon bacilli Welch bacilli anaerobes and other bacteria including fusiform bacilli *and spirochetes* which are very frequently found seem to be secondary invaders which probably intensify *and prolong the* disease and cause the unpleasant odor so often noted The lesions caused by *Bacillus tuberculosis* are regarded separately from lung abscess

Except for the few specific infections listed above which may be regarded as ' primary infections though in perhaps all cases some preceding condition is *present most* cases of lung abscess are brought about by the invasion of a mixture of ever present mi

croorganisms which grow in tissue altered or damaged by a variety of causes Such damage may arise from inflammation materials aspirated into the lung emboli or other causes

The most common causes of abscess are (a) operations on the oropharynx (tonsillectomy) especially under general anesthesia (b) acute pulmonary inflammations (c) abdominal operations, (d) neoplasms of the bronchi lungs or esophagus (e) bronchiectasis (f) trauma contusion from penetrating wounds or fractured ribs (g) foreign body in the bronchus (h) bacteremia

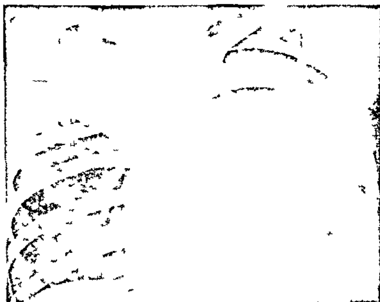

Fig 91—Acute abscess of the lung with cavity formation fluid level and peripneumonitis in the right upper lobe The large area in the left lung interpreted as being pneumonia, later broke down to form another abscess It represents the early stage of lung abscess The patient had granulocytopenia and died (Courtesy of Dr K. Kornblum)

from infection elsewhere in the body (i) infarcts and (j) submersion in and/or aspiration of liquids

Lung abscess rarely occurs as a complication of lobar pneumonia unless secondary invasion with staphylococci occurs but minute multiple abscesses are often found post mortem especially in patients with Type III pneumococcus pneumonia in whom the disease has been prolonged Abscess apparently occurs more often in certain forms of atypical pneumonia (Fig 91) particularly that caused by Staphylococcus aureus (Fig 92) in which miliary abscesses are present early Abscess following abdominal operations may be due either to emboli or it may follow postoperative pneumonia, atelectasis or the aspiration of vomitus or other foreign bodies Rupture of pus through the diaphragm may be a cause Recent statistics indicate that the apparent increase in pulmonary neoplasms causes an increasing number of secondary lung abscesses The development of a secondary abscess may be the first indication of neoplasm as well as of foreign bodies

Pathology—The right lung is more often involved than the left and the lower lobes more than the upper ones Both lungs are usually involved in cases of multiple abscesses Associated conditions such as empyema pleurisy pyopneumothorax and pericarditis often occur Amyloid disease pyemia abscess of the brain and mediastinitis may follow in prolonged cases

Unless the abscess is primary the lesions associated with the previous disease are present In many cases the earliest changes may be those of pneumonia or pneumonitis (Fig 91) but in others the process begins with necrosis Abscesses may be single or multiple and in certain cases multiple abscesses coalesce to form a large single one (Fig 92)

The size of pulmonary abscesses varies from that of a pinhead to that of an orange The larger cavities if *recent or advancing* have ragged walls of necrotic lung tissue surrounded by a zone of hyperemia and con tain purulent blood stained and often fetid fluid debris the older lesions gradually be come enclosed by a thick fibrous wall Em bolic abscesses often numerous are located as a rule just beneath the pleura These often start as irregular infarcted areas which at first are firm grayish red in color and surrounded by a zone of intense hyper emia, but as their centers soften they may *perforate into a bronchus or through the* pleura in the latter case giving rise to pyo pneumothorax

Drainage *through the bronchus may* be obstructed by formation of granulation tis sue by the bronchial mucosa The abscess may heal after its evacuation and *leave no* trace it may disappear by spontaneous re sorption without drainage or it may be come walled off with *fibrotic tissue and* result in a chronic abscess or in a cyst Fibrosis in and around the area with dense pleural adhesions, calcification and de formity of the chest wall is common

Symptoms—As a rule the early symp toms of 'primary' lung abscess are regarded as those of bronchitis grippe or pneumonia By the end of the second week however the patient may suddenly expectorate pus which may or may not have a foul odor Cough is present sooner or later in almost all cases and may be the first symptom If the abscess ruptures cough is distressing Pain referred to some part of the chest is often noted early It may resemble pleuritic pain and is made worse by deep breathing *Small hemoptyses may occur* Fever is pres ent from the onset and may be high later the temperature curve becomes remittent *and characteristic* of sepsis with chills sweats loss of weight and strength and anemia Clubbing of the fingers may be *noted after a few weeks* No doubt many lung abscesses occur without ever being rec ognized They may run their course with *spontaneous cure* by evacuation or absorp tion

Lung abscess developing after aspiration

Fig 92—Multiple abscesses in both lungs following staphylococcic pneumonia The roentgenogram was made twenty-eight days after the onset of pneumonia The left lung where the process began is honeycombed with large rarefied areas in one of which a fluid level can be seen There is infiltration of the right upper lobe with a cavity at the level of the third rib The patient raised 300 to 500 cc of sputum at about this time and had intermittent high fever but recovery followed two weeks later (Reimann H A The Pneumonias W B Saunders Co 1938)

trauma or obstruction begins a few days to several weeks after the primary episode The abscess may be unsuspected until it ruptures into a bronchus or is discovered by roentgenography Usually high intermittent fever is present there is prostration toxemia cough and expectoration The sputum may vary in amount from a few cubic centimeters to a liter It is purulent perhaps blood tinged and settles into several layers or occasionally it may be chocolate colored from the presence of old blood There may be no odor or it may be offensive from putrefactive changes Shreds of lung tissue and myriads of bacteria are demonstrable by microscopic examination

The contents of an amebic abscess of the liver which has perforated the lung often may be recognized from the bitter taste of the bile and by its ochre-yellow color or anchovy sauce appearance Microscopic examination of such sputum reveals bile acid crystals elastic tissue recognizable liver cells and occasionally amebas In favorable cases specifically treated recovery may take place after several weeks with complete healing More often the disease becomes chronic in spite of treatment with frequent exacerbations especially if drainage is blocked

In chronic abscess of the lung many of the systemic symptoms may disappear but cough and copious sputum persist for months or years Hemorrhages may occur Frequent exacerbations and remissions are common Dyspnea cyanosis cachexia pyemia brain abscess mediastinitis empyema and amyloid disease may follow

Physical Signs—The physical signs of lung abscess as a rule are not helpful especially if the abscess is small or deeply located An abscess near the surface may occasionally be detected by a slight dulness and changes in the breath and voice sounds Tympany amphoric or cavernous breathing and egophony are absent unless cavitation occurs and the abscess is evacuated Rales may be present early before cavitation begins or afterward in the presence of pneumonitis There may be slight cyanosis clubbed fingers and dyspnea In chronic cases the physical signs depend upon the amount of fibrous tissue formed and on the character of the complications

Diagnosis—The diagnosis may be first indicated by the expectoration of foul pus following a brief illness as already described Physical examination may aid but often definite physical signs are lacking Exploratory puncture for diagnosis is contraindicated because of the danger of spreading the infection Bacteriologic examination of sputum should always be made since in some cases a single variety of organism may be involved and specific treatment indicated

Bronchoscopy should be performed in cases of obscure etiology to detect a possible foreign body or tumor

Fig 93—A large well-drained thick walled single cavity in the left upper lobe surrounded by a narrow area of peripneumonitis Another roentgenogram two weeks later showed enlargement of the cavity with spread to the other lung but a third plate one month later showed great improvement

The abscess developed twelve days after tonsillectomy Treatment consisted of bronchoscopic drainage

Roentgenography is of great value in diagnosis and without it many lung abscesses would not be diagnosed especially in those who recover Films should be made at frequent intervals both anteroposteriorly and laterally to locate the abscess follow its progress and to detect any lesions behind the heart and the domes of the diaphragm Early in the disease there may be found a homogeneous density (Fig 91) which after a few days may show rarefaction in the center and still later cavitation (Figs 92 and 93) with or without a fluid level The periphery of the shadow is soft and fuses

with the surrounding tissue unless pneumonitis is present If *the cavity is full of* pus or necrotic tissue and without drainage typical rarefaction is of course, absent The lesions may disappear without trace or they may leave permanent scars

The intrapulmonary injection of radiopaque iodized oil is often helpful in mapping out diseased areas and in differentiating the disease from bronchiectasis but when there are large amounts of sputum the oil may fail to reach the abscess In chronic cases cavitation with a fluid level is more *sharply outlined due to encapsulation* with fibrous tissue and perhaps with bone formation Extensive fibrosis and distortion are common Roentgenograms greatly aid in making the decision for surgical intervention

In *differential diagnosis* pulmonary tuberculosis bronchiectasis pneumonia foreign body in the bronchus lung tumors perforating empyema amebiasis and cysts are of especial *importance* A history of eating peanuts has aided in diagnosis in several of my patients who were unaware of having aspirated one Foreign body abscess should be suspected in small children and in the aged especially after operation on the nose and throat

Specific *infections like tuberculosis Bacillus friedländer* infection fungus infections and amebiasis can be diagnosed by identifying the causative organism The differentiation *from bronchiectasis and massive ne*crosis may be difficult or clinically impossible Many elderly patients who die from lung abscess also have pulmonary cancer In cancer the following symptoms are helpful in diagnosis edema of the arm or face displacement of the heart paralysis of the recurrent laryngeal or phrenic nerve symptoms of involvement of the brachial plexus or the development of Horner s syndrome rapid reaccumulation *of pleural fluid* if tapped and bronchial stenosis as discovered by roentgenography or bronchoscopy Malignancy should be particularly suspected in persons more than forty five years of age but it *may* occur at any age Exploratory thoracotomy may be indicated for diagnosis

Prognosis—Many lung abscesses heal spontaneously (Figs 92 and 93); others respond to no treatment whatsoever The *prognosis always* is better in persons otherwise healthy and less than forty years of age and especially in children Patients may recover spontaneously from abscesses which follow pneumonia and from those due to *metastatic or postoperative infection* but authorities differ greatly as to the frequency with which this occurs Some claim that recovery is spontaneous in 7 per cent others in 60 per cent of their cases The outlook is *most favorable when the abscess opens* into the bronchus and drains freely Such may heal and leave no scar Empyema following the rupture of superficial abscesses into the pleural cavity may be cured by surgical drainage In untreated fatal cases, if not a feature of septicemia there is an *average life expectancy of three years* during which time many of the symptoms present are those of the secondary pulmonary fibrosis and bronchiectasis Lung abscesses secondary to amebic liver abscesses have a *fair prognosis if specific treatment* is used Embolic abscesses which arise from a septicemia usually run a rapidly fatal course

Treatment—The best results of treatment are obtained by applying general rules to the circumstances of each case individually The chief factors governing treat*ment are* (1) *the underlying* cause of the abscess (2) the duration of the abscess (3) the general condition of the patient (4) the site and extent of the lesion (5) *the specific etiologic agent* and (6) the presence of complications in the lung and pleura

Acute abscess is best treated without surgery unless the course of the disease is stationary or if after a month or more the patient is losing ground There is usually a tendency to spontaneous healing and in more than 60 per cent of cases rest or postural treatment will suffice

During the acute stage of pulmonary abscess rest in bed in the open air and a nutritious diet are as *essential as in* pulmonary tuberculosis This sometimes is the only treatment necessary It is of greatest importance to remove the cause if one can be found In chronic cases supportive treatment is necessary with especial attention to maintaining suitable diet and preventing *anemia*

Drug therapy by mouth or administered intrabronchially is of very little value except for the treatment of amebic abscess (see page 843) Inhalations of vapor of compound tincture of benzoin and various preparations of creosote in steam serve only to deodorize or mask the unpleasant odors or taste There are no effective antiseptics Sulfanilamide or its compounds are of no value unless the hemolytic streptococcus or pneumococcus plays a role Arsphenamine has no place in the treatment since the spiral organisms often present are not believed to be of primary etiologic importance and even if they were there is no evidence to show a specific effect of the drug upon them Vaccine treatment and treatment with roentgen rays have not been helpful Patients should not be poisoned with potassium iodide because of the presence of yeasts or fungi in the sputum They are usually secondary invaders growing in necrotic tissue

After the abscess has ruptured into a bronchus but not while the condition is still acute postural drainage repeated three or four times a day should be practiced Abscesses of six months duration or longer rarely heal spontaneously For such drainage through the bronchoscope is sometimes satisfactory but only if drainage is obstructed by thick exudate foreign body or granulomatous tissue or edema of the bronchial mucous membrane This may be the only form of nonsurgical drainage possible when the abscess is surrounded by an extensive zone of pneumonitis or a thick fibrous wall

Collapse of the lung by artificial pneumothorax has been used with some success in the treatment of pyogenic abscesses but only when they are deeply located This procedure however by kinking the bronchus may hinder drainage and always makes difficult or impossible a later more radical operation It is not suitable for routine use Many therefore prefer phrenicectomy or phrenicotomy Some authorities would not collapse the lung under any circumstances since this procedure has been followed occasionally by rupture of the abscess into the pleural cavity with the production of severe and sometimes fatal empyema

Radical surgery should be considered if the abscess is superficial and if after three to six weeks (some recommend even three months) of medical treatment there has been little improvement, if all pleural pain has ceased and if the abscess as seen in the roentgenogram has become well demarcated Earlier operation is recommended if there is considerable cough with nausea anorexia insomnia and rapid loss of weight and strength, but in general it should not be attempted while the patient is critically ill for at that stage the postoperative mortality is high The fatality rate may be as low as 10 per cent if the operation is preceded by a period of a few weeks of rest in bed with postural drainage An operation not later than at the end of two months may forestall many complications and also lessen the degree of fibrosis and bronchiectasis likely to follow The operation should if possible be done under local anesthesia and free, dependent open drainage obtained If the patient s condition permits a two stage drainage operation is preferable Late surgical drainage that is two to seven years after the onset at which time a dense fibrous wall will have formed around the abscess is much less successful than earlier operations and the mortality is high For chronic abscesses lobectomy and pneumonectomy are being used with more and more success The relative merits of operative procedures are critically reviewed by Maxwell

Prevention —The recent knowledge accumulated concerning the frequency of lung abscess after certain types of operations should lead to the adoption of measures to reduce the hazard of this complication to the utmost

Every precaution should be taken at all periods of life to prevent the aspiration of foreign bodies both in consciousness and especially during coma from any cause

MASSIVE NECROSIS OF THE LUNG

(*Gangrene of the Lung*)

Occurrence—Primary necrosis of the lung or death en masse with putrefaction of lung tissue is a rare condition unless one includes certain lung abscesses Secondary necrosis occasionally develops in the walls of tuberculous cavities pyogenic abscesses, and bronchiectatic dilatations and in areas of pulmonary infarction and pneumonic consolidation

Etiology—The organisms responsible for necrosis have not with certainty been identified The presence within the necrotic tissues of the fusospirochetal micro organisms is not rare and because of them attention has been called to the association of pulmonary necrosis with dental caries pyorrhea alveolaris and especially with operations on the mouth Spirochetes however often are absent, but it is generally admitted that anaerobic organisms are important

Pulmonary necrosis sometimes develops in the absence of all other recognizable causes Marked debility however, seems to be an almost necessary predisposing factor, since *so many patients who develop it are diabetic* insane or convalescing from protracted fever Necrosis rarely follows primary pneumonia *but more often it follows aspiration* pneumonia it is the rule when a cancer of the esophagus perforates into the lungs The walls of a bronchiectatic cavity especially if the dilatation is due to pressure on its bronchus not infrequently becomes necrotic Gangrene may develop in a septic infarct Necrosis of the lung and abscess of the brain are frequently associated conditions

Pathology—Diffuse pulmonary necrosis may convert the greater part of one lobe into a greenish black mass in the center of which forms a ragged cavity filled with foul smelling material

In the circumscribed form the focus may be single or multiple the lower lobe is more commonly affected than the upper and the peripheral more than the central portions of the lung If due to an embolus the plugged artery *can sometimes be found* Gangrenous areas at first are greenish brown in color and firm but soon break down and form cavities Each area is surrounded by a zone of consolidation this in turn by one of deep congestion on the periphery of which is a halo of intense edema which is sharply marked off from the surrounding normal tissue These areas show little or no tendency to spread When the liquefaction of the tissue is rapid, the walls of the contained blood vessels may rupture before they become closed by thrombosis with profuse hemorrhages the result Embolic processes not infrequently start from these areas The liquefied tissue usually excites an intense bronchitis Pyopneumothorax may develop

Symptoms and Course—The presence of necrosis in such pulmonary lesions as those *of pneumonia abscess infarction usually* is unmistakable since both the odor of the breath and that of the sputum are characteristic and may permeate the entire house but localized areas of necrosis which have no free communication with bronchi may remain quite unsuspected during life The same is true of the areas of necrosis seen in some cases of diabetes mellitus even when they have outlets for they may be odorless The fetor of gangrenous sputum usually is much more offensive than is that of fetid *bronchitis, bronchiectasis or abscess of the* lung nevertheless it alone is insufficient for diagnosis The sputum usually is profuse and, *if collected in a tall glass* cylinder separates into three or more layers the top thick and frothy, the middle thin liquid and sometimes with a greenish or a brownish tint and a greenish brown sediment in which are shreds of decomposing lung tissue Blood often is present in the sputum but as a rule it is much altered The sputum microscopically contains elastic fibers in abundance granular matter pigment grains fatty crystals and micro organisms

Among the general symptoms of diffuse necrosis are fever usually of moderate grade rapid pulse and prostration which usually progresses until the patient dies Circumscribed areas develop more gradually and show *little tendency to spread* Patients with such lesions generally die later of exhaustion Profuse often fatal hemorrhages are not rare Some patients however recover even those who have expectorated large fragments of lung tissue In such cases the fetor of the breath lessens the sputum becomes more and more purulent and dimin

ishes in amount and the clinical picture improves

In cases of necrosis the physical signs of intense bronchitis are often present also those of cavity if the latter lies in a superficial location Limited circumscribed gangrenous areas difficult to detect by physical diagnosis *may be discovered by roentgenography*

Prognosis —Massive pulmonary necrosis *usually is a terminal condition*

Treatment —The treatment of necrosis of the lung is on the whole very unsatisfactory and consists chiefly of regulation of the diet personal *hygiene to lessen the odor and* careful nursing Necrosis associated with *Bacillus welchii* should be treated early with specific antisera which should be used in large quantities It is possible that sulfanilamide may prove effective but no reports of its trial for gas bacillus infection of the lung are available

Among the various measures attempted to mask the odor of the breath and sputum are an intratracheal spray of weak dilutions of phenol and inhalations of vaporized creosote compounds They are usually unsatisfactory The patient may wear over the mouth and nose an inhaler containing solutions of phenol or guaiacol The following solution injected *intravenously every other* day is often helpful sodium iodide 0 15 Gm (2½ grains) guaiacol 0.3 Gm (5 grains) alcohol 2 cc (*¼ drachm*) *distilled water* 20 cc (⅔ ounce) The sputum cup may be deodorized by a 1.3 per cent solution of chloral hydrate and the mouth rinsed with a weaker solution of the same drug If the patient's condition is good and the necrotic region *is superficial and well localized* surgical intervention is desirable In cases of unilateral necrosis artificial pneumothorax has been recommended by some and phrenicectomy by others Many object to these treatments on the ground that they interfere with the drainage of the cavity Certainly they should not be employed if the lesion is near the pleura or if there is free fluid in the pleural or pericardial sac

PULMONARY FIBROSIS

Etiology and Occurrence —Pulmonary fibrosis is the result of pathologic processes in which the substitution of fibrous tissue for the normal lung parenchyma takes place The changes may be local and limited to a relatively small area or diffuse involving either one or both lungs *The fibrosis may* be limited chiefly to the bronchi or bronchioles (bronchiolitis obliterans) and blood *vessels (vascular fibrosis pulmonary arterio* sclerosis page 849) the interlobar septums the alveolar walls (chronic interstitial pneumonia) the pleura or it may involve several *or all of these areas (pulmonary cirrhosis* pneumonoconiosis page 853)

Local fibrous changes also surround or replace pulmonary tumors areas of atelectasis infarcts pneumonia abscesses bronchiectatic cavities masses of pigment gummata, irradiated areas (Fig 94) and hydatid cysts and form a wall around encapsulated and inspissated empyemas Scar tissue which produces pleural thickening may extend throughout the lung Fibrous changes not only surround aneurysms and new growths but also appear in the regions of the lung *which are compressed by these conditions*

Local fibrosis is the essential element in the healing of tuberculosis It is therefore *most often found in the apexes of the lungs* but other causes may also be operative there In cases of chronic pulmonary tuberculosis *in which the tendency to heal keeps* pace with the process of necrosis but does not surpass it the most of one or both lungs may in the course of years be converted into a dense mass made up chiefly of fibrous tissue

Diffuse fibrosis may be the result of chronic disturbances (Fig 95) of the lungs bronchi or pleura It may be a rare sequel after pneumococcic lobar pneumonia in which the normal process of resolution fails and the exudate is replaced by fibrous tissue A number of filtrable viruses particularly influenza virus attack the interstitial tissues of the lung which may favor the subsequent development of fibrosis

Diffuse pulmonary fibrosis may develop in some cases of long standing chronic passive congestion emphysema and asthma Fibrosis follows the inhalation for years of certain dusts the particles of which stored

in the interlobular lymphoid tissue become walled in by fibrous tissue (see Pneumonoconiosis page 853) These changes are especially marked at the hilum areas and bases of the lungs Fungous infections of the lung radiation pneumonitis and the inhalation of irritating gases may result in fibrosis

In about 25 per cent of all cases of pulmonary fibrosis however no definite cause is discovered for its presence either during life or at necropsy

Symptoms and Course—Pulmonary fibrosis is essentially a chronic disease extending over many years Its symptoms vary

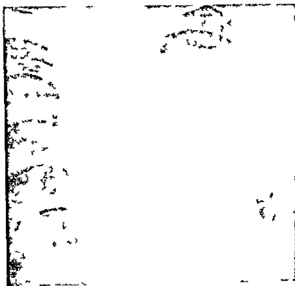

Fig 94—Localized pulmonary fibrosis after intensive radiation given for neoplastic metastasis in the lung Fibrosis was found at necropsy in the dense area in the left lung (Courtesy of Dr L G Rigler)

considerably according to the stage and extent of the process The most common are chronic cough cyanosis and slight shortness of breath If bronchiectasis develops there is paroxysmal cough abundant sometimes fetid expectoration and occasionally hemoptysis Some cases of fibroid phthisis can be distinguished from nontuberculous pulmonary fibrosis only by the signs in the former of a cavity at one apex or by the presence of tubercle bacilli in the sputum often the final diagnosis can be made only at necropsy Many patients with fibroid phthisis when once the condition has become established have shortness of breath only on exertion are able to do light work and enjoy fairly good health In advanced cases hypertrophy of the right ventricle dilation of the pulmonary conus (cor pulmonale) and so called pulmonary hypertension (page 849) result from the increase in peripheral resistance brought about by a reduction of the capillary bed in the lungs Death occasionally is due to pulmonary hemorrhage or intercurrent infection but is

Fig 95—Diffuse pulmonary fibrosis in a woman of 36 who had had asthma for sixteen years Her complaint was progressive weakness dyspnea, asthma and slight pain in right upper quadrant Dusky cyanosis of the upper part of the body was first mistaken for hemochromatosis and for polycythemia The veins of the ocular fundi neck forearms and abdomen were greatly distended and the liver enlarged There were musical squeaks wheezes and rales in both lungs and constant dyspnea even at rest but no acropachy Erythrocytes 5 200 000 leukocytes 9 000 hemoglobin 105 per cent pulse rate average 100 respiratory rate 27 blood pressure 105/70 and there was slight fever

Roentgenogram shows numerous tents and depression of the diaphragm emphysema, thickening of the hilum increased bronchovascular markings enlarged cardiac pulmonic conus and diffuse fibrosis throughout especially dense in the midportion of both lungs

The cyanosis slight polycythemia, enlarged pulmonary conus and evidence of myocardial insufficiency suggest Ayerza s disease (p 850)

more commonly the result of gradual heart failure

Physical Signs—When the disease is unilateral and well established the affected side of the chest is retracted deformed and immobile the intercostal spaces are narrowed or obliterated the ribs may even overlap the shoulder is drawn down the muscles of the shoulder girdle are atrophied and there is scoliosis of the spine its concavity toward the lesion Litten's sign is absent

on the affected side The mediastinum is pulled toward the side involved

Mensuration of the affected side shows a decrease in its size and the tape demonstrates its limited expansion on inspiration The note on percussion varies it may be absolutely flat everywhere particularly at the base or apex but if the bronchi are large and sacculated the note in the axilla may be tympanitic or amphoric On the normal side the percussion note usually is hyperresonant and the breath sounds and tactile fremitus are exaggerated Cardiac murmurs are not uncommon particularly late in the disease after the right ventricle has begun to fail In some cases the chief symptoms from the first are cardiac in nature the evidence of gradual heart failure In bilateral disease the signs are those of chronic asthma with no outstanding characteristic signs Rales are not prominent unless heart failure or infection is present Many of the long bones especially those of the fingers may show pulmonary osteoarthropathy (acropachy)

Diagnosis —The diagnosis of pulmonary fibrosis is seldom difficult but in the absence of a clear history it may be impossible to say what the primary process was Tuberculosis may be hard to exclude as the cause yet even in long standing cases of phthisis tubercle bacilli usually are present in the sputum and there is often evidence of this disease in the other lung The roentgenogram is of great assistance in diagnosis (Figs 94 and 95)

Treatment —All those measures so useful in cases of pulmonary tuberculosis such as dry climate wholesome diet and cod liver oil are of value in the early stage of pulmonary fibrosis Any focal infections which might favor the progress of secondary processes should be eliminated Usually it is because of some intercurrent affection or for an aggravation of the cough that the patient seeks relief Nothing can be done for fibrosis once it has fully developed The patient should if possible live in a mild climate and avoid exposure to wet and cold Cardiac weakness is a common feature of this disease and should receive proper attention At times the putrefaction of the contents of the dilated bronchi is distressing and requires the same measures recommended for massive necrosis (page 847) For the disfiguring deformities of the chest which sometimes develop various gymnastic exercises have been suggested, especially those which immobilize the sound while inflating the diseased, pulmonary tissue Roentgen ray therapy is useless

PULMONARY ARTERIOSCLEROSIS

(*Pulmonary Hypertension*)

According to some writers pulmonary arteriosclerosis and pulmonary hypertension are dependent upon each other and there is controversy as to which is cause and which is effect Obviously, a diagnosis of arteriosclerosis can only be proved at necropsy and there is no way of measuring the blood pressure in the pulmonary or lesser circulation The diagnosis is made by inference The signs and symptoms of both conditions however are apparently similar Pulmonary arteriosclerosis is classified into primary and secondary forms The cause of the rare primary form is unknown but in a few cases syphilis or rheumatic fever has been suspected The secondary form may follow numerous long standing hyperemic states such as accompany bronchiectasis tuberculosis congenital cardiac anomalies thoracic deformities emphysema asthma passive congestion from chronic cardiovascular disease or any other condition causing peripheral resistance in the pulmonary circulation In limited forms there is thickening of the intima and degeneration of the media of the pulmonary artery and partial or complete obliteration of its branches The arterioles and capillaries may be involved especially in the secondary form Pulmonary arteriosclerosis may of course be included in general systemic arteriosclerosis or may be a part of pulmonary fibrosis described in the preceding section

Symptoms —The condition is often unnoted clinically or mistaken for some other disease or masked by the primary disease

The chief symptoms are dyspnea vertigo, hemoptysis and precordial pain There is increased venous pressure accentuation of the second pulmonic sound, dilatation and hypertrophy of the right side of the heart, of the pulmonary conus and of the superficial veins also cyanosis enlargement of the liver, lowered renal function and infarction of the lungs Pulsation in the intercostal spaces, a bruit heard all over the chest and an up and down movement (dance) of the diaphragm are said to occur The absence of rales in the presence of an enlarged liver ascites and edema is also said to be of importance in diagnosis Cough with sputum is commonly present Characteristic changes are noted in roentgenograms of the chest (Figs 95 and 96) The condition may last for years and terminate in myocardial failure or by intercurrent infection The name *Ayerza s disease* is applied to the advanced stage when cyanosis and polycythemia are present (Fig 95) Giesbock s disease to some cases if there is cyanosis and hypertension, and still others are included in the Osler-Vaquez syndrome

The treatment is chiefly that for the primary condition if one is present otherwise it must be palliative Rest and inhalation of oxygen are temporarily useful Residence in an equable climate is desirable

RADIATION PLEUROPNEUMONITIS

High voltage roentgen therapy applied to the thorax for various purposes often causes pneumonitis and pleurisy with effusion The susceptibility of the lungs of different persons to roentgen rays varies considerably some are affected by small doses others tolerate massive doses If radiation is continued over an extended period as it often is for neoplasm pulmonary and pleural fibrosis develops

The milder forms of pneumonitis or pleuritis are symptomless and can be recognized only by roentgenograms In more severe forms symptoms resembling an acute in

fection of the lungs appear about a week after radiation Pleuritic pain dyspnea on exertion and dry cough are noted The symptoms usually disappear soon if no further radiation is given but in some instances the condition may result in permanent fibrosis

The diagnosis is made on the history symptoms and roentgenographic findings (Fig 94) There is no treatment except to prevent further injury from roentgen rays by proper shielding or directing of the rays

HOBART A REIMANN

CHEMICAL PNEUMONIA

Chemical pneumonia is the term applied to acute pulmonary lesions caused by the inhalation of irritating gases particularly chlorine bromine ammonia sulfur dioxide phosgene chlorpicrin lewisite mustard gas various acetates diethylphthalate and ethylene halides Gases inhaled in strong concentration may lead to sudden death from shock or to intense catarrhal inflammation pulmonary edema and asphyxia Less severe exposure results in a condition similar to that of the acute infectious pneumonias Bacterial invasion and pneumonia may follow Lung abscess necrosis bronchiectasis emphysema or fibrosis may result

The treatment for the severe forms is like that for shock for the mild form it is the same as for pneumonia (page 116)

HOBART A REIMANN

ALLERGIC PNEUMONIA

Transitory lung infiltration with eosinophilia (Loeffler s pneumonia) is believed to be the result of the reaction of sensitized lung tissue to an antigen Persons suffering from asthma allergic rhinitis and urticaria occasionally develop the signs and symptoms of a mild inflammation of the lung Slight fever cough with sputum and moderate leukocytosis with a high proportion of eosinophile cells are found The signs in the lungs may be minimal or absent but a massive infiltration may be seen in a roentgenogram The shadow may disappear in a few days

The condition is important because it may be mistaken for tuberculosis coccidioidomycosis or pulmonary ascariasis and because it can so often be prevented by removal of the offending sensitizing agent or relieved with epinephrine before secondary invasion by bacteria occurs

NEW GROWTHS IN THE LUNGS

Among the new growths of the lungs may be mentioned carcinoma sarcoma the enlarged lymph nodes of Hodgkin s disease and the leukemias as representing the most common malignant forms and dermoid cysts adenoma chondroma osteoma neurofibroma and lipoma as benign growths

Benign growths may give no indication of their presence for years unless as they enlarge they press on important organs or give rise to secondary infections and ulceration or to obstruction of the air passages They are often discovered first by roentgenography or at necropsy

Malignant Growths —Carcinoma of the lung both primary and secondary or metastatic is the most important of the neoplastic diseases The secondary form occurs more often but both seem to be increasing in incidence It is a source of controversy whether the increase is apparent or real and much evidence favors both views Primary cancer of the lung occurs next in frequency to cancer of the gastro intestinal tract and causes from 5 to 10 per cent of deaths from cancer Of all cases 9 per cent develop between the ages of 21 and 40 and 72 per cent between 41 and 60 years

The *cause* of course is unknown but all factors are said to have one quality in common namely chronic irritation The irritation may be caused by chemical mechanical bacterial radioactive and perhaps thermal means (Simons) Some believe that chronic irritation plays no role

The majority of primary cancers arise from the bronchial epithelium a few from the bronchial mucous glands The right lung is more often involved than the left and the upper lobes more often than the lower Tumors of the larger bronchi may lead by occlusion to bronchiectasis atelectasis or

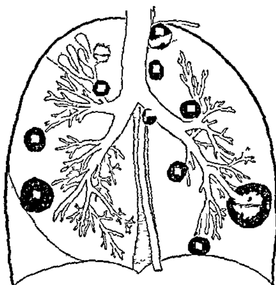

Fig 97—Illustrating the pathogenesis of symptoms and signs in primary carcinoma of the lung 1 Tumor near the pleura may produce pleurisy and serous or bloody pleural effusion 2 In this area a tumor may be silent for months 3 If a bronchus is occluded atelectasis and dilatation of the distal bronchi may occur with bronchiectasis pneumonitis or abscess formation 4 A tumor in the apex may cause erosion of a rib paralysis of the sympathetic trunk causing a Horner's syndrome pain in the arm and partial paralysis of the ulnar and median nerves by invading the first dorsal root of the brachial plexus and invasion of adjacent structures 5 Pressure here may cause paralysis of the recurrent laryngeal and phrenic nerves 6 Incomplete obstruction of a large bronchus often causes unilateral wheezing and may cause obstructive emphysema 7 Ulceration of the bronchial mucous membrane gives rise to blood streaked sputum or recurrent hemorrhages 8 Tumors may undergo central necrosis with abscess cavitation and bronchial fistula 9 Irritation of the diaphragmatic pleura may cause pain of typical phrenic nerve distribution 10 Invasion of the esophagus with obstruction or ulceration may occur (Churchill E D, in Christopher's Textbook of Surgery Ed 2 W B Saunders Co)

abscess but more often they leave the bronchus open Pleural effusion pneumonia abscess or gangrene, and purulent bronchitis commonly occur

Symptoms —Metastatic lung cancers usually develop in the interstitial tissues of the hilum and cause few symptoms unless by pressure they close one of the bronchi Primary neoplasms grow insidiously the first *indication often being given by extrathoracic metastasis* A few start acutely with dyspnea hemoptysis and pain but usually the symptoms and signs are not those of carcinoma alone but rather of its secondary effects (Fig 97) The symptoms resulting from these changes are those of *atelectasis* bronchiectasis obstruction or abscess These account for the following symptoms noted in order of frequency cough sputum pain in the chest dyspnea weakness and emaciation fever hemoptysis dilated thoracic or cervical veins and cyanosis Other less common symptoms are night sweats vomiting hoarseness and acropachy

Cough is the most common symptom and is usually accompanied by an ordinary mucoid or mucopurulent sputum Cough once started usually persists regardless of treatment Wheezing respiration may be heard Pain may be local or referred to the shoulder arm or epigastrium Dyspnea which may appear early or late occurs in 59 per cent of cases especially if pleural effusion is present Low fever is present at some time in about 50 per cent of cases Weakness is common and cachexia develops late in the disease Edema of the arm or face displacement of the heart paralysis of the recurrent laryngeal and phrenic nerves or the brachial plexus rapid reaccumulation of bloody pleural fluid if tapped, Horner's syndrome and evidence of bronchial stenosis are all important signs

The *physical signs* of pulmonary cancer often are indefinite, since the tumor is usually covered by a layer of normal pulmonary tissue Those most common are wheezing or bronchial breath sounds and unusually well heard voice sounds in the conduction of which these solid tumors greatly aid If however the tumor invades the pleural surface or ulcerates through the bronchial mucosa pleural effusion bronchiectasis or lung abscess may arise In cases with pleural effusion the heart may or may not be displaced

Primary cancers of the upper lobe early present certain almost pathognomonic physical signs almost complete flatness and a sense of resistance in the infraclavicular fossa and diminished or absent vesicular breath sounds but no tubular breathing no amphoric sounds and a few or no rales

The life expectancy in cases of primary

cancer of the lung varies from one and one half months to five years the average expectancy is nine months after the appearance of symptoms

Diagnosis —The possibility of the presence of a primary cancer of the lung should always be borne in mind when patients more than 40 years of age who before have been well prior to one year complain of any of the following symptoms loss of weight not easily accounted for the sudden appearance without evident cause of cough pain in the chest shortness of breath or hemoptysis dyspnea in the absence of cardiovascular disease or a severe persistent boring pain in the chest, not accompanied by a pleural rub or signs of aneurysm

Today about 50 per cent of all cancers of the lung are diagnosed clinically though in the great majority of instances the diagnosis is made too late for efficient treatment Twenty years ago only 5 per cent were recognized before necropsy The diagnosis should be made however in 90 per cent of cases if careful consideration be given to the history roentgenograms physical examination bronchoscopy biopsy of lymph nodes or of tissue removed through the bronchoscope and study of the cells of any pleural effusion present The possibility of cancer should be considered in all cases of lung abscess bronchiectasis recurrent or unresolved pneumonia empyema hemorrhagic pleurisy and suspected tuberculosis Against tuberculosis are the facts that a primary cancer usually begins at the root of the lung and the sputum contains no tubercle bacilli

Roentgenograms make the diagnosis in 93 per cent of all cases Primary films often show that the diaphragm is unusually high on one side but if artificial pneumothorax is produced the tumor may become evident A characteristic finding is a large dense shadow involving a part or the whole of a lobe with a hazy irregular edge and associated with shadows at or extending to the hilum Bronchoscopy with the removal of a piece of tissue often permits an early diagnosis but in many cases such a procedure is unnecessary

Treatment —In early cases in which there is no evidence of metastasis wide surgical excision (lobectomy or pneumonectomy) offers the best chance of cure Numerous successful operations have been reported with 'cures lasting from one to six years Bronchoscopic removal endobronchial diathermy cauterization and implantation of radon seeds have been reported to be successful in a few cases but the feasibility of such measures is limited to bronchogenic carcinomas Radiotherapy can only be considered as palliative at present Symptomatic treatment is all that can be given in advanced cases

PNEUMONOCONIOSIS

Definition —Pneumonoconiosis is a generic term comprising all the chronic fibrous reactions arising in the lung as a result of the prolonged inhalation of excessive quantities of injurious mineral dusts such as those of sand granite flint asbestos The term is used at times to describe pulmonary fibroses resulting from inhalations of dusts which are mixtures of substances in which the relative pathogenicity of each constituent is undetermined Many of the pneumonoconioses are scarcely to be considered as diseases since they may exist without producing symptoms or impairing physical efficiency as in the case of anthracosis chalicosis siderosis etc On the other hand dusts containing high concentrations of finely divided silica produce serious forms of pulmonary fibrosis of great medical and economic importance (silicosis) Admixture of carbon gypsum and hematite with silica in dust results in a modification of the reaction to silica retarding or inhibiting its noxious effects

The silicates vary greatly in pathogenicity —some are apparently inert others mildly pathogenic while still others may even exert a retarding effect upon the action of free silica Of the fibroses caused by silicates that due to asbestos (asbestosis) is probably the only one of importance though certain

investigators believe that some of the seri cites are pathogenic

As a rule the effects of inhalation of organic dusts are not included in the scope of the pneumonoconioses Such dusts may excite allergic reactions, they may introduce infection or result in local irritant or toxic actions

SILICOSIS

Definition —Silicosis is a chronic condition of the lungs caused by inhalation of air containing finely divided particles of silica (SiO_2) in sufficient quantity and over a sufficient period of time to produce fibrous nodules *in the walls of the alveoli which are* readily recognizable in roentgenographs of the chest and in pathologic specimens Clinically the process is recognizable as a disease only in its advanced stages either by increased dyspnea on exertion or by the symptoms of tuberculosis to which it predisposes

Etiology —Silica is widely distributed in nature since it makes up a large part of the rocks and minerals which form the earth's crust It occurs free as SiO_2 and combined in the forms of silicates Quartz which is one of the most common forms of free silica occurs abundantly in granite and other rocks In consequence of this one might expect a high incidence of silicosis among workers in mines and *tunnels and in stone* cutters There are however a great number of other industrial processes in which workers may be exposed to dust containing considerable amounts of free silica Among these are listed the manufacture and use of abrasives sandblasting chipping buffing of metals metallurgic processes ceramic manufacturing glass making enameling and the molding of metals In 1930 it was estimated that more than a million industrial workers were potentially exposed to a silicosis hazard and that half of this number were exposed to truly dangerous quantities of airborne silica

Knowledge concerning the pathogenic effects of free silica in dust has come from several sources From the South African gold mines *from* the granite industry at Barre Vermont from the anthracite mines in Pennsylvania, from the gold mines of Ontario from the lead mines and sewer tunnels of New South Wales have come reports of long continued studies of dust conditions and their effect upon the workers in these industries Methods have been devised for counting dust listing the number of particles the distribution of their sizes and their composition These data are correlated with the health records of the workers, including their death rate from tuberculosis, and with the incidence of pneumonoconiosis as revealed by x ray survey

Another important source of knowledge concerning the injurious effects of dust is the work of the Saranac Lake Laboratory under the direction of Dr Leroy U Gardner who employs a technic in which animals *are kept in dusts of known concentration* for long periods of time so that the pathologic changes produced in their lungs may be observed From studies of this kind it appears that the relative dangerousness of dusts is roughly proportional to the concentration of free silica in the different varieties Other constituents of the dust are either inert or exert a modifying effect upon the reaction of the lungs to the free silica

The size of the particles is very important It is doubtful whether particles larger than 10 microns enter the finer air passages The greatest danger therefore lies in particles less than 10 microns and it is probable that the most dangerous size is that less than 3 *microns There are several reasons for this* The larger particles settle out of the atmosphere more quickly than do finely divided particles Also the injurious effect of silica is believed to be exerted after partial solution in other words its injurious effect is chemical rather than mechanical Since the smaller the particle the greater is the relation of surface to mass it is obvious why the smaller particles go more readily into solution

The most common method employed for the enumeration of particles of dust in air is the so called light field method by means of which it is possible to enumerate only particles more than 1 5 microns *in size* Recently a dark field method has been introduced which reveals a much larger number of particles less than 1 5 microns There is still much to be learned about the patho

genic aspects of these very minute particles since dark field counting is not yet standardized or generally employed

Donald Cummings of the Saranac Laboratory has summarized the present available data in regard to permissible dust concentrations Information from field studies in various parts of the world indicates that a normal man might work in pure crystalline silica dust for many years without impairing his health provided the concentration did not exceed 5 000 000 particles per cubic foot of air as determined by the light field counting method This has been called by Cummings the primary threshold The duration of exposure is of course a most important factor The rate at which silicosis develops under the same conditions varies with different persons In general it may be said that in individuals working in dust containing 5 000 000 particles of pure silica per cubic foot it would require from five to twenty years for the development of demonstrable silicosis The rate of development however does not appear to vary directly with the concentration of silica but increases slowly with elevations of the dust concentration up to a certain level at which a marked acceleration is noted Concentrations of dust in which there are more than 100 000 000 particles per cubic foot of air are extremely hazardous and this has been called by Cummings the secondary threshold" a value above which silicosis might be expected to develop with great rapidity Under such conditions nodular fibrosis might occur in as short a time as two years As a general rule from fifteen to twenty years working exposure to 15 000 000 or 20 000 000 particles of pure crystalline silica are required to produce demonstrable silicosis The Code of the state of Wisconsin provides that a maximum permissible concentration of dust is 15 000 000 particles containing not more than 35 per cent free silica and further provides that as the percentage of silica increases the permissible concentration must be proportionately decreased Tentative proposals have recently been made in New York State to define the permissible limits of dust during rock drilling The limits proposed range from 50 000 000 particles with 5 per cent free silica to 5 000 000 particles when more than 40 per cent is silica

Predisposing Causes—Reports from many parts of the world indicate that all races are susceptible Sex is not a factor—women develop the disease when exposed to the same conditions as men The age factor is very difficult to evaluate Surveys indicate that the incidence of silicosis is higher among young miners if the dust concentrations are high and higher among old miners when the dust concentrations are low These deductions however probably relate to the rapidity of labor turnover, rather than to an effect of age upon susceptibility to the disease Among predisposing causes, past and present respiratory infections are of great importance particularly those of the nasal sinuses Emphysema old pleurisies pneumonia and bronchitis are of importance in so far as they impair the dust removal mechanism of the lung The efficiency of the filtering mechanism of the nose appears to play an important role Some observers believe that mouth breathers are more susceptible than those with normal nasal passages The fact remains however that individual variations in susceptibility are poorly understood

Silicosis and Tuberculosis—In England the tuberculosis rate is higher among workers in dusty trades being three to ten times as high as the rate for all occupied and retired males Gardner has made the statement that At least 75 per cent of the human beings who develop silicosis die of tuberculosis which may make its appearance at any stage of the disease Such a statement however requires some qualification In anthracosilicosis and siderosilicosis of coal and iron miners the action of silica is somewhat modified the disease requires a longer time to produce disability and the incidence of active tuberculosis is less than in the case of unmodified silicosis

Modifying Factors—Apart from the modifying effect of coal dust and iron ore on the reaction to silica there is increasing evidence that other dust constituents are not entirely inert In a recent study of the gypsum industry Gardner has found evidence of a protective action of gypsum dust when it is mixed with silica Surveys of the cement industry have revealed a very low incidence of silicosis among the workers This has been taken by some to mean that there is a protective substance but it seems

more likely that the low incidence of silicosis is due to the small amount of free silica in cement dust Rapidly developing silicosis in the abrasive soap industry has been attributed to the accelerating effect of alkali This conclusion should be accepted with reservations, since it is also possible that the rapid development is due to an extraordinary proportion of particles of silica less than 0.5 micron in size the enumeration of which is not possible by the light field method

Morbid Anatomy—For purposes of description it is important to distinguish between the lesions of simple silicosis and silicosis with infection In *simple silicosis* the *essential lesion is the silicotic nodule* Typical nodules are 2 to 5 mm in diameter and are scattered more or less uniformly throughout the parenchyma of the lung under the pleura and in the nodes at the hilum They are avascular laminated fibrous whorls and when disseminated are usually situated at the entrance to a lobule They punctuate the perivascular lymphatic pathways between the alveoli and the hilum and between the alveoli and the pleura at the periphery of the lung There is frequently associated a perilymphatic fibrosis The alveoli may be thick walled and dilated The lymph nodes at the root of the lung are usually fibrosed and in their periphery may show typical laminated whorls As the process advances these minute miliary nodules may become agglomerated and ultimately may form dense fibrous rubbery masses of tissue replacing considerable numbers of lobules As fibrosis and atelectasis progress in the more fibrous portion of the lung the remaining portions may undergo considerable emphysematous change often with the formation of large blebs The pleura usually shows thickening and is frequently adherent

In the advanced forms with dense fibrosis and emphysema hypertrophy of the right ventricle is often observed associated with some tendency to dilatation of the pulmonary conus

Silicosis with Infection—The most important infection associated with silicosis is tuberculosis which may have antedated the silicosis in a latent apical focus or which may develop simultaneously with it or may arise from an exogenous source at any time during the course of silicosis The anatomic findings vary in accordance with the above possibilities

Tuberculosis in silicosis tends to be chronic The character of the reaction consists in formation of granulation tissue and scar Caseation and cavitation are late manifestations as a rule The tubercle bacilli are frequently very difficult to detect, either by staining or by inoculation

All the usual manifestations of tuberculosis may occur and the tuberculous infection may be extensive enough at times to obscure the underlying silicosis The combination frequently presents the picture of an organizing pneumonic area about the silica nodule which thus appears larger and less sharply circumscribed than in simple silicosis The coalescence of such nodules leads to larger dense fibrotic masses

Modified Silicosis—Nonsilicious dusts such as coal, emery, carborundum gypsum and iron produce collections of phagocytes in alveoli without thickening of the adjacent wall They may accumulate slowly in the lymph nodes and may be deposited about the lymphatics under the pleura and throughout the lung

In anthracosilicosis and siderosilicosis one finds perilymphatic fibrosis The greater the free silica admixture with coal or hematite the more hyalinization is seen If the free silica in dust is high nodular fibrosis is found

Symptoms—Simple silicosis may progress to advanced stages with no symptoms other than a tendency to shortness of breath This is noted at first on moderate exertion but as the disease progresses it may occur on less and less severe exertion It is not accompanied by orthopnea unless asthmatic paroxysms intervene The occurrence of orthopnea suggests an associated cardiac condition Riddell has pointed out that if severe dyspnea is produced by effort in two patients one with silicosis and one with heart disease the silicotic will be able to lie flat immediately after and the cardiac patient will not

Cough with uncomplicated silicosis is not a prominent symptom When it occurs it is noted chiefly in the morning and it is either dry or very slightly productive of mucoid

sputum Cough may occur while actually working in dust due to irritation of the nose and throat without reference to the existence of silicosis Men who have worked for a day in dust usually expel dust-discolored sputum on the following morning

When cough is a prominent symptom it is almost sure to denote complicating infection and in such cases it is usually more or less productive Even when tuberculosis is present tubercle bacilli are difficult to find in the sputum unless cavitation has occurred and this is usually a late phenomenon The fibroid tuberculosis most frequently accompanying silicosis may not be characterized by much fever or night sweats tachycardia or weight loss This is not an invariable rule but its frequent occurrence gives the impression that the silicotic fibrosis retards the symptoms of tuberculous activity

The physical diagnosis of simple uncomplicated silicosis is practically impossible The physical signs in simple silicosis are those of emphysema hyperresonance on percussion diminished intensity of breath sounds with prolongation of low pitched expiration Occasional rhonchi and fine and scattered medium coarse rales are heard in the interscapular regions and bases When signs other than these are elicited they are indications of a complicating infection rather than of the underlying silicosis One is repeatedly surprised by the great discrepancy between physical signs and the extensive pulmonary disease revealed by roentgenographs

In simple silicosis the circumferential expansion of the chest is usually diminished while good excursions of the diaphragm may persist In advanced cases with dense fibrosis and emphysema the diaphragmatic excursion is reduced When active infection is present expansion is impaired more than the extent of the lesions as revealed in roentgenographs would lead one to expect

Pathologic Physiology—The vital capacity of the lungs is a good measure of expansile capacity In estimating normality of vital capacity the West formula based upon surface area is most unsatisfactory Hurtado has found a better formula for prediction based upon measurements of roentgenographs of the chest made at full inspiration

The total pulmonary capacity (vital capacity plus residual air) tends to be reduced in proportion to the extent of the fibrosis The vital capacity is less than normal and the residual air is greater (when measured by the technic of Christie) In advanced cases the accuracy of the measurement of residual air may be open to question However when large values for residual air are observed there is severe functional impairment When the residual air exceeds 40 per cent of the total capacity the saturation of the arterial blood with oxygen is usually found to be less than normal

When patients with silicosis perform muscular work the volume of air expired per minutes is greater than in the case of normal men performing the same work Their breathing is more rapid and more shallow

The range of ventilation per minute found when normal men perform measured amounts of work (from 200 to 800 Kg m per minute) while riding a bicycle ergometer has been fairly well established When silicotics perform similar amounts of work the comparison of the ratio of ventilation to vital capacity with that of normals gives an index of the tendency to dyspnea

The maximal ventilation which an individual can attain may be estimated from the vital capacity on the assumption that 42 per cent of the vital capacity is used in each respiration thirty seven times a minute The pulmonary reserve is the difference between the actual ventilation per minute and the maximal When patients with silicosis perform measured amounts of work the ventilation per minute comprises a higher percentage of their maximal capacity than in the case of normal men performing the same work Thus their pulmonary reserve is less than normal for two reasons the minute ventilation is excessive and the maximal ventilation is limited in proportion as the vital capacity is reduced

The behavior of the pulmonary ventilation in silicosis is of precisely the same character as that observed by Harrison in heart disease In both instances it seems probable that interstitial changes in the lungs have

resulted in disturbances in the Hering Breuer reflexes

In advanced cases of silicosis with extensive fibrosis and emphysema hypertrophy of the right heart and dilatation of the pulmonary conus may be observed This phenomenon is best explained on the assumption that the capillary bed of the lungs has been reduced sufficiently to increase the peripheral resistance in the lesser circuit In about half the cases in which this *cor pulmonale* is found the electrocardiogram reveals right axis deviation and abnormality of T waves or S T intervals in leads II and III

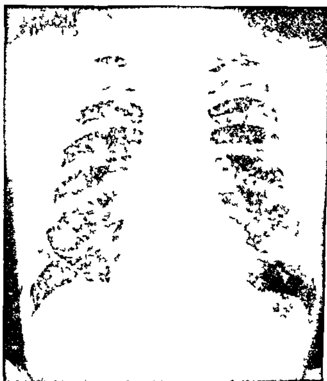

Fig 98—Silicosis showing beginning agglomeration in the left lower lobe with resulting secondary emphysema (Dark area just above left leaf of diaphragm)

Diagnosis—The two essentials to a diagnosis of silicosis are an accurate occupational history and characteristic roentgenographic findings The occupational history should cover all occupations in which the patient has been engaged and the duration of employment in each In connection with those occupations which are dusty as much information as possible should be obtained as to the amount and character of the dust and the extent to which protective devices were used

The roentgenographic findings have certain characteristics which, when taken with a reliable occupational history and the clinical findings warrant making a probable diagnosis of silicosis The roentgenograph alone cannot decide the diagnosis since there are a number of conditions which may give similar appearances

In roentgenographs of the lungs in simple silicosis there are seen discrete round shadows not exceeding 5 to 6 mm in diameter having clear cut borders They are fairly uniformly distributed in each lung The visualization of the process is greatly enhanced by stereoscopic viewing of the roentgenographs In addition to these appearances enlargement of the shadows of the tracheobronchial nodes is noted

In infective silicosis in addition to the picture of simple silicosis the following changes may be seen localized discrete densities mottling in which the shadows vary in size and have ill defined borders soft nodulation in which the nodules have fuzzy borders with irregularity in distribution

In advanced cases massive dense shadows appear with surrounding portions of increased radiotranslucency caused by dense

fibrosis and adjacent emphysema Frequently seen also are evidences of pleural thickening and adhesion and tenting" of the diaphragm

The diagnosis of silicosis is impossible before the discovery of shadows of silicotic nodules Before this stage is reached a positive or even probable diagnosis cannot be made Developing silicosis may be suspected from the observation of serial roentgenographs showing progressive changes when occupation is known to involve a dust hazard but the diagnosis should not be made until nodular shadows are seen

Differential diagnosis involves the exclusion of other causes which may give similar roentgenographic appearances Simple diffuse nodular silicosis must be differentiated from miliary tuberculosis by the absence of fever tachycardia and wasting which characterize the latter Similarly metastatic tumors the mycoses and tularemia must be excluded

The finding of silica particles in the sputum is of little value in diagnosis unless the patient has been excluded from all contact with silicious dusts for some time

Prophylaxis of silicosis is one of the major concerns of the industrial physician in charge of workers in dusty trades Systematic studies should be made of the air suspended dusts at breathing levels of the workers When excessive dust concentrations are found and especially when the percentage of free silica is high cooperation of managerial and engineering departments must be enlisted to improve ventilation and remove dust

Many devices are now available for the protection of workers in rockdrilling sand blasting chipping and grinding and foundry work These protections are constantly being improved

It is important not only to see that adequate devices are provided but to insist upon their use and frequent inspection in order to keep them in usable condition

Periodic examination of workers exposed to dangerous dusts is highly important The exclusion of men with open tuberculosis is a great protection to other workers Serial roentgenographs should be made at intervals

Treatment —There is no specific treatment for simple silicosis Infective silicosis should be dealt with as tuberculosis The *prognosis* in many cases of silicosis with tuberculosis is not as hopeless as many have assumed it to be When tuberculosis occurs with a modified silicosis in an iron or coal miner, or a foundry worker suitable treatment may cause arrest of the disease

Among copper and gold miners sand blasters and granite cutters the outlook is serious if tuberculosis develops It is important however for the patient to receive the same treatment as he would if silicosis were not present

EMPHYSEMA

Definition —Emphysema is a condition in which the alveoli of the lungs become distended or ruptured The term is also applied to a condition in which there is air in the subcutaneous and interstitial tissues and which has nothing in common with the other form except the name

The disease was described by Floyer and by Morgagni in the eighteenth century but not until publication of the classic description of Laënnec and of Jenner was its clinical significance or its pathology well understood

Etiology —*Obstruction of the Air Passages* —Emphysema may arise from any condition which causes distention of the lungs and is particularly favored by circumstances which allow greater interference with expiration than with inspiration Experimentally great distention of the lungs can be produced without damage if the pressure is quickly released the elasticity of the normal lung causing it to return to its usual position If even moderate distention be maintained however changes in the lung become permanent with disturbance of local circulation and loss of elasticity In the distended position of the lung anything which increases

intrapulmonary pressure such as coughing or straining may advance the process

Clinically acute emphysema may in certain rare cases be caused by a *valvelike obstruction* which admits some air without allowing it to escape A flapping diphtheritic membrane or the tenacious mucous exudate of chronic bronchitis acts in this way Such true valvular action, although most effective in producing rapid distention is by no means necessary The very nature of the respiratory mechanism enables any partial obstruction to produce emphysema Inspiration is accomplished by powerful contraction of the diaphragm and the intercostal muscles Expiration under ordinary circumstances is passive and even when aided by the accessory muscles is not so forceful as inspiration Consequently in inspiration air passes the obstruction with comparative ease while expiration is prolonged difficult and often incomplete A gradual distention of the lungs results *Asthma chronic bronchitis and* whooping cough are frequent causes of emphysema It may also arise from tumors in the mediastinum or from partial obstruction of the larynx

Changes in the Size and Shape of the Thorax—Because of the negative pressure in the pleural spaces the lungs tend to adapt themselves to the size of the thorax Thus in conditions such as Paget s disease and acromegaly which are characterized by bony overgrowth of the thorax stretching of the lungs sometimes of extreme degree *may occur as an entirely secondary phe*nomenon

In 1858 Freund advanced the theory that *many cases* of emphysema might be the result of a primary disease of the costal cartilages consisting of hyperplasia and premature ossification causing enlargement of the thorax a conception which has excited much comment but which has never been established Kountz and Alexander have shown that many of the cases which occur in older people and which have often been called in the literature 'senile emphysema may be dependent upon a *disease of the* intervertebral disks In this condition the spine is at first straightened causing an elevation of the ribs and of the thorax and a displacement of the lungs to a position higher than normal Later, disease of the vertebrae themselves may cause angulation of the spine with kyphosis which still further increases the deformity and abnormal position of the thorax and lungs In some instances pathologic stretching of the lungs may result through this mechanism Although it operates *most often in patients* past middle life it may occur in young individuals with Pott's disease and other kyphotic deformities of the dorsal *spine Recently Kerr has* emphasized this condition as a part of a syndrome which occurs in obese middle aged individuals and which he considered one of the most important seen in the practice of adult medicine In this condition the diaphragm may be pulled downward by the increased weight of the abdominal contents with a consequent mechanical disadvantage in pulmonary ventilation which may simulate to some extent the changes of obstructive emphysema

Changes in the Pulmonary Vessels—The *elasticity* of the lungs *may be impaired by* nutritional disturbances resulting from insufficiency of the pulmonary circulation and particularly from arteriosclerosis of the smaller branches of the pulmonary vessels

Compensatory emphysema results from an overstretching of the airholding portion of the lung when for some reason other parts are not functioning It is always secondary and indicates no essential disease of the distended portions It is seen in uninvolved lobes during pneumonia and occurs with patchy distribution in bronchopneu*monia and tuberculosis* With fibrosis of the lung or with long standing pleurisy it may become permanent

Age—Emphysema due to asthma chronic bronchitis or other partial obstruction may not become striking enough to attract attention for several years after the onset of the primary condition Except in cases from these more obvious obstructive causes the disease is generally seen after middle life *although occasionally it may* develop in young children

Heredity—The possibility of hereditary emphysema has been much discussed Although there are numerous examples of the occurrence of emphysema in several members of the same family many of these may be attributed to hereditary allergy Evidence that individuals are born with weak

elastic tissue and a consequent tendency to early distention of the lungs is not convincing

Morbid Anatomy —The essential pathologic lesion in obstructive emphysema is the loss of elasticity and rupture of the alveoli In the more advanced stages there is fusion of several alveoli into one large air sac Large blebs may be found on the surface of the lung Upon opening the chest the lungs appear to be larger than normal They usually collapse slightly, but may remain distended They are pallid and seem to contain little anthracotic pigment Pallor and distention are often more marked at the apices and at the sternal margins The lungs have a feathery consistency and pit on pressure *Microscopically* the air sacs are greatly distended The epithelium of the alveoli undergoes fatty changes In the bronchi there are evidences of chronic inflammation and there is peribronchial fibrosis Dilatation of the air sacs and smaller bronchi is always noted

The stretching of the alveoli results in changes in the pulmonary capillaries which may disappear before the atrophy of the walls is complete Arteriosclerosis of the pulmonary arteries is not extensive in cases which have resulted from obstructive causes but may be an important feature in a few cases which develop without obvious clinical causes This is usually most notable in the smaller arterioles

The relationship of emphysema to the development of *cor pulmonale* has been much debated Kountz and Alexander have shown that in some patients dying with extreme emphysema the right heart may appear entirely normal More recent observations by these authors and by Scott and Garvin have demonstrated that both in experimental animals and in men strain upon the right side of the heart is an essential part of the disease In advanced cases this may be accompanied by an unexplained hypertrophy of the left ventricle Right heart failure is seen in more advanced form in emphysema associated with disease of the pulmonary arteries

One of the most important functional changes occurring in emphysema is an elevation of the intrapleural pressure which may approach that of the atmosphere

Morbid Physiology —The extensive anatomic changes of hypertrophic emphysema interfere seriously with the exchange of gases in the lungs In advanced stages the oxygen saturation of the arterial blood may be diminished from the normal of about 95 per cent to 90 or 85 per cent or less even during rest During exertion the saturation may be even more greatly diminished There is interference also with the passage of CO_2 from the lungs and a consequent marked increase in the CO_2 tension in both arterial and venous blood

Several factors contribute to this disturbance of function The destruction of air spaces with the diminution of alveolar surface may be of fundamental importance and the degenerative changes in the remaining alveoli may interfere with diffusion of gases It has been suggested by Christie that when the muscles of inspiration are held in an inspiratory position and the lung is inelastic inspiratory effort is ineffective and response in breathing is limited to outlying alveoli many of which are functionless The residual air (the amount of air remaining in the lungs after the deepest possible expiration) is increased so that the air column through which diffusion of gases must take place is greater than normal The vital capacity of the lungs is diminished in the advanced disease to less than half the normal There is some evidence that in emphysema the volume of the dead space is increased The minute volume and the rate of respiration are usually slightly greater the depth of each respiration somewhat less than normal Both the relatively shallow breathing and the increase in dead space render each breath less effective and add to the difficulty All of these factors tend to prevent proper exchange of gases when the patient is at rest while during exercise their effect becomes more evident The oxygen saturation of the arterial blood decreases rapidly and CO_2 accumulates In spite of this the volume of breathing does not increase so much as in normal individuals no doubt because of the diminution in the vital capacity and the mechanical limitations of the emphysematous lung This inability is well demonstrated when an emphysematous patient breathes a 7 per cent mixture of CO_2 and air With this powerful respiratory stimulus a normal individual may increase the vol

ume of breathing six to seven times a patient with advanced emphysema, on the other hand may no more than double the respiratory volume even when higher percentages of CO_2 are employed

One of the more important functional changes occurring in emphysema is an elevation of intrapleural pressure which may approach that of the atmosphere This interferes with the return of blood to the heart and may result in increased venous pressure which is not attributable to heart disease

Symptoms —The onset of emphysema is insidious and the lesions may be well advanced before symptoms become apparent The first evidence is puffiness and shortness of breath on exertion with perhaps moderate cyanosis In winter there may be persistent bronchitis with an increase of dyspnea As times goes on bronchitis becomes more severe breathlessness may result from slight exertion and cyanosis may occasionally become extreme and out of all proportion to the degree of dyspnea or the other symptoms In no condition except congenital heart disease is there such marked cyanosis in ambulatory patients During the course of emphysema attacks of acute bronchitis in association with the advancing emphysema may simulate asthma Throughout the early stages of the disease the patient is much more comfortable in summer but as the process advances there is troublesome bronchitis with chronic cough in both winter and summer Sooner or later symptoms which simulate closely the picture of cardiac decompensation add to the distress of the patient Dyspnea increases orthopnea develops with edema of the extremities In cases complicated by pulmonary sclerosis these symptoms may in part be due to insufficiency of the right heart Ordinarily however the picture probably results from a combination of inefficient lungs anoxemia and increased venous pressure Extraordinary cyanosis may occur in the terminal stage Intercurrent pneumonia is not an infrequent cause of death

Physical Signs —*Obstructive Emphysema* —Chronic emphysema may usually be recognized by inspection The breathing is more rapid and shallow than normal Even in the early stages there may be moderate cyanosis of the lips or lobes of the ears which increases with slight exertion The appearance of the chest is characteristic the marked increase in the anteroposterior diameter gives to the thorax a barrel shape There is an upper dorsal kyphosis The chest is held in permanent inspiration so that the shoulders appear elevated and the neck shortened The intercostal spaces are widened The sternum and intercostal cartilages are prominent The costal angles become obtuse and in extreme degrees of the disease are almost straight There are often small venules along the line of attachment of the diaphragm The apical impulse of the heart cannot be seen but there is usually marked pulsation in the epigastrium During inspiration the chest is elevated as one piece and there is little or no measurable expansion

Upon *palpation* the tactile fremitus is feeble but not lacking The cardiac apex cannot usually be felt To *percussion* there is an increased resonance sometimes almost a tympany The limits of the lung resonance may be extended in some instances to the costal margin The heart dulness may be obliterated and the areas of hepatic and splenic dulness greatly diminished or lost Upon *auscultation* the breath sounds are feeble and are often obscured by the rales of bronchitis Expiration is prolonged and may be four times the length of inspiration Harsh rhonchi may be heard In obstructive emphysema the lungs are so stretched as to force the diaphragm into a position of almost full inspiration Breathing may be entirely thoracic and fluoroscopic examination reveals little motion of the diaphragm with breathing Heart sounds are distant There may be an accentuation of the second pulmonic sound The action of the heart is rarely irregular

Emphysema Dependent on Shape of Thorax —Since in this type of emphysema there is usually less actual stretching of the lungs cyanosis and other signs of functional disturbance are apt to be less marked In the senile cases the thoracic spine is usually straighter than normal the ribs and entire thorax are elevated The breathing tends to be abdominal and in the fluoroscope the diaphragm descends normally or more than normally with inspiration In the advanced cases dorsal kyphosis is a prominent feature

In the syndrome emphasized by Kerr there is great abdominal adiposity which leads to shifting of the line of gravity forward in the erect position The major portion of the dorsal spine is moved backward the thoracic curve is exaggerated, the normal lumbar lordosis becomes more marked and the dorsal and lumbar spines tend to assume the shape of an S

Treatment —Emphysema is a progressive disease the rapidity of its progress depending upon the stress to which the damaged lungs are subjected In the obstructive cases dependent upon asthma the control of the allergic condition offers the chief indication for treatment Particular care must be exercised to prevent the occurrence of bronchitis Whenever possible the patient should live in an equable mild climate during the late fall and winter and should remain until the spring is well advanced Unfortunately such care is rarely possible and to the vast majority of patients who must remain at work during the winter months advice must be given concerning the avoidance of sudden chilling and wetting Clothing should be warm but so adjusted as to prevent perspiration within doors or chilling without Sudden changes in temperature involved in going outdoors from an overheated room on a cold winter day are particularly dangerous The feet should be carefully protected against wet Dusty occupations heavy lifting or severe prolonged exertion should be avoided

Great help has been obtained by many patients with emphysema through the use of an abdominal belt as devised by Alexander and Kountz A newer belt described by Kerr provides flexibility by means of elastic webs inserted in the sides It is effective both in obstructive and postural emphysema and is simpler to construct and easier to wear than the original belt The proper adjustment of such a belt tends to increase intra abdominal pressure causes demonstrable elevation of the diaphragm and more effective breathing Medication does not affect the course of the disease but may provide symptomatic relief Ephedrine in doses of ⅜ to ¾ grain (25–50 mg) may be helpful in relieving bronchial spasm not only in allergic cases but also in those with accompanying bronchitis With the appearance of orthopnea and peripheral edema, digitalis may be tried but is seldom effectual in relieving the symptoms

DISEASES OF THE PLEURA

PLEURISY

(*Pleuritis*)

Definition.—Pleurisy is an inflammation of the pleural membranes parietal visceral or diaphragmatic This inflammation may heal often with resulting pleural thickening and adhesions or may lead to effusion of serous or serofibrinous fluid or to the formation of pus Three chief clinical types are recognized (1) *acute fibrinous pleurisy* (pleuritis sicca), (2) *pleurisy with effusion* (pleuritis serosa pleuritis serofibrinosa) (3) *empyema* (pleuritis purulenta) As a late result of extensive or recurrent pleurisy widespread adhesions and thickening of the pleura (sometimes with persistent effusion) occur resulting in limitation of respiration displacement of the heart and other organs and pain on effort This condition has been

described as (4) *chronic pleurisy* (pleuritis fibrosa)

Etiology —While pleurisy has been ascribed to exposure to cold, or conceivably may result from lodgment of infectious organisms in the pleura without the production of disease elsewhere in the body, it is usually secondary to disease in other tissues of the body It may arise (*a*) by extension of a disease process in the lung as in pneumonia or tuberculosis in which it frequently is a characteristic part of the symptomatology of the disease pulmonary infarcts or abscesses or malignant disease of the lung may extend to the pleura (*b*) by extension of inflammation from adjacent organs as in pericarditis mediastinitis or subphrenic abscess (*c*) by metastatic blood borne infections as in septicemia (*d*) as a symptom in the course of diseases such as chronic nephritis, gout rheumatism or leukemia In pleurisy following trauma or fracture the mechanism is usually obvious although even here the pleurisy may be infectious the trauma and exposure merely reducing local tissue resistance sufficiently to allow the infection to develop

Bacteriology —In pleurisy occurring in the course of a clearly marked disease such as lobar pneumonia septicemia or advanced tuberculosis the bacteriology is commonly that of the primary disease although secondary bacterial invaders may also be found In those cases in which the pleurisy is an early and predominant feature bacteriologic study may indicate the nature of the underlying disease The sputum the chest fluid, and the blood afford material for study The so called primary serofibrinous pleurisy is usually tuberculous (80 per cent) and is secondary to a pulmonary focus sometimes quite small Microscopic examination of such fluids will demonstrate the tubercle bacillus in about 30 per cent and guinea pig inoculation will determine the presence of tuberculosis in still others Serous effusions may occur in streptococcal pneumococcal or other bacterial infections and in such fluids the organisms may or may not be demonstrable Subsequent aspirations may yield purulent fluids In empyema following lobar pneumonia the pneumococcus is usually found

In epidemics of respiratory infections of the past twenty five years, pleurisy, often purulent has been frequent Streptococci have been most often found as in epidemics of septic sore throat or in the streptococcal pneumonias following measles and influenza The organisms predominating in the empyemas following influenza in army camps during World War I varied according to the kind of organism prevalent in the camp communities In some camps streptococci predominated with few instances of pneumococcal infection In others pneumococcal infection was more frequent In a few a peculiarly virulent staphylococcal pneumonia with occasional empyema was met with At Camp Upton Brooks and Cecil found the incidence of empyema was 36 per cent in the streptococcal pneumonias as compared with 11 per cent in the pneumococcal cases In a study of 137 empyemas in a nonepidemic period Lord found pneumococcus in 39 4 per cent and streptococcus in 20 4 per cent At Camp Custer during the influenza epidemic there were very few pneumococcal pneumonias and most of the empyemas were due to hemolytic streptococci Among other organisms occasionally found in the fluid of empyema are *Streptococcus mucosus capsulatus* Friedlander's bacillus *Staphylococcus aureus* typhoid bacillus diphtheria bacillus and *Bacillus pyocyaneus*

In purulent pleurisy resulting from extension of abdominal infection such as appendicitis or liver abscess, from rupture into the pleura of a lung abscess or from perforation into the pleura of malignant disease of esophagus or stomach organisms such as the colon bacillus and various saprophytes may be found

Morbid Anatomy —The inflammatory changes in the pleura may be unilateral or bilateral sometimes involving only a small circumscribed area or, extending over the entire pleural surface of one side In acute fibrinous pleuritis the membrane loses its luster becomes roughened because of deposition of fibrin, and is more vascular than normal Proliferation and detachment of the endothelial cells of the pleura occur with increase of the subendothelial connective tissue and leukocytic infiltration of the inflamed parts In some instances the fibrin forms a very thin membrane in others a

thick creamy layer Fibrinous pleuritis may leave behind little or no evidence of its presence, or the parietal and visceral pleurae may become bound together by adhesions which in some instances are so dense that they entirely obliterate the pleural cavity These adhesions may produce displacements of the mediastinal structures and heart

In serofibrinous pleurisy in which in addition to the fibrinous exudate there is an exudation of serum from the capillaries the quantity of the effusion may vary from a small amount to as much as 4 or 5 liters The fluid is sometimes encysted by interlobar or parietal adhesions The exudate has a specific gravity of 1 016 or more is rich in albumin often coagulates quickly on standing contains leukocytes red blood corpuscles and endothelial cells and chemically it may contain cholesterin uric acid and sugar In most cases it has a light straw color but it may sometimes be hemorrhagic In empyema the fluid is turbid or purulent and contains large numbers of polymorphonuclear leukocytes and often large flakes of fibrin

When the quantity of effusion is large the lung is much compressed In extreme cases the lung may be reduced to a small flattened airless mass which lies in the posterior and upper part of the chest approximately between the levels of the third and sixth dorsal vertebrae Downward displacement of the diaphragm depresses the liver and the spleen As the result of the increased intrapleural pressure on the affected side the heart is displaced toward the opposite side a change which is more marked in left than in right sided effusions The heart however is displaced as a whole and even in extensive effusions on the left side there is no rotation of its apex The other contents of the mediastinum such as the great vessels and the trachea are also displaced

When suppuration in the pleura (empyema) has occurred the pleura is grayish white or yellowish in color and may be greatly thickened The inflammation may be general or circumscribed with sacculation of the fluid Interlobar encapsulation of the effusion is not uncommon If long continued the inflammation may lead to penetration of the soft tissue of an intercostal space with a resultant external discharge of pus (empyema necessitatis) or the inflammation may extend into the interstitial tissue of the lung Pleural suppuration may also extend to the pericardium or to the mediastinum and be complicated by endocarditis cerebral abscess or thrombosis of the intrathoracic or other vessels While rarely empyema may extend downward through the diaphragm it is much more common for infection in the abdomen such as that of appendicitis to extend upward to the pleura The exudate of pneumococcal empyema contains large flakes of fibrin that of streptococcal empyema very little fibrin In empyema following abscess or gangrene of the lung or perforation of a viscus the fluid may be putrid The specific gravity of empyema fluid varies between 1 024 and 1 030 or even higher and the predominating cell is the polymorphonuclear leukocyte The color of the fluid is usually yellowish sometimes with a greenish tinge The consistency is thin at first and later so thick as to render aspiration difficult

ACUTE FIBRINOUS PLEURISY

Symptoms—Acute fibrinous pleurisy usually has an abrupt onset manifested by a stitch or pain in the side Some types of dry pleurisy usually the more chronic are not painful Acute pleurisy often marks the onset of acute infectious disease such as lobar pneumonia or occurs in the course of a clearly defined infection or is an early event in pulmonary tuberculosis which has hitherto produced no recognizable signs

In other cases the symptoms are limited to those caused by the pleurisy itself Often there are prodromal symptoms such as cough and expectoration In some cases the onset of pain is accompanied by a chill The pain is stabbing or cutting in character is increased by deep respiration is commonly aggravated by coughing or by change of position and is usually located in the fifth or sixth intercostal space in the midaxillary line or beneath the scapula Pain may be felt in the shoulder in apical pleurisy or referred to the neck or abdomen in diaphragmatic pleurisy The location of pain caused by pleural irritation depends on the

location of the pleurisy with reference to the nerve supply of the pleura to our knowledge of which much has been added by the excellent studies of Capps *The visceral pleura* has no pain sense, the parietal pleura secures sensory fibers from the intercostal nerves and pain is felt over the region of the pleura involved The central portion of the diaphragmatic pleura is innervated by the phrenic nerve and pain originating here is referred to the neck and skin and tissue overlying the trapezius muscle, supplied by the third and fourth cervical nerves The peripheral and posterior portions of the diaphragmatic pleura are innervated by the last six thoracic nerves and pain from irritation of these portions of the diaphragmatic pleura is referred to the lower chest wall lumbar region epigastrium, or lower abdomen Such referred pain may render diagnosis difficult by simulating that of certain abdominal diseases such as inflammation of the gallbladder or of the appendix

About 75 per cent of the patients suffer from a cough which is usually dry hacking and suppressed and which aggravates the pain The respiratory rate is usually increased as the result of the patient s effort to lessen the coughing and pain by limiting the excursion of the lung Fever is often present the temperature rising to 102° or 103° F

Physical Signs —The patient shows evidence of distress and lies on the affected side with the shoulder depressed and the upper part of the spine deflected toward that side *in order to reduce the expansion of the lung* The respiratory rate is increased so that the pulse respiration ratio may approach that of pneumonia If there is much fibrinous exudate, the tactile fremitus is decreased and the expansion of the affected side is limited Occasionally there is marked tenderness of the skin over the region of the pleurisy and a *friction rub* is often palpable The percussion note may be unimpaired but if there is much exudation of fibrin its resonance will be decreased

The rubbing together of the roughened surfaces of the pleura produces an audible to and fro leathery *friction rub* synchronous with the respiration except during the early stages of the disease when superficial crepitations—the so called *pleural crackles*—can be heard The most common site of the friction rub is in the midaxillary line in the fifth or sixth interspace When the pleurisy is near the border of the heart the friction sound may be synchronous with the movements of the heart It is then called a *pleuropericardial* friction rub The intensity of the breath sounds is less on the affected side though they still retain their vesicular character

In the majority of cases the leukocyte count varies from 8000 to 12 000 In about 40 per cent of the cases it is above 12 000 sometimes reaching 20 000 When the pleurisy is a complication of pneumonia the figure may be still greater

The *progress of acute fibrinous pleurisy* varies The acute stage with fever lasts about ten days and the entire course of the disease is usually about three weeks When it is more prolonged the pleura often remains considerably thickened Serofibrinous pleuritis may develop with decrease or disappearance of pain

Diagnosis —In most cases the diagnosis of acute fibrinous pleurisy can be made readily from the history of sudden onset of pain in the side which is increased by respiration and coughing and from the presence of friction rub Diaphragmatic pleurisy however, is often difficult to diagnose The conditions to be differentiated from fibrinous pleurisy include pericarditis herpes zoster pain in the side caused by irritation or pressure on nerves in spondylitis or by a mediastinal tumor acute inflammatory conditions of the abdomen and acute myositis

The *pericardial friction rub* is heard best along the left border of the sternum in the third and fourth interspaces is synchronous with the heart movements and is not influenced by respiration The best method therefore for differentiating a pleuropericardial from a pericardial friction rub is to auscultate while the patient inspires as deeply as possible and holds his breath and again while the patient expires as fully as possible and again holds his breath in order to compare the character of the friction rubs in these two phases

The herpetic eruption establishes the diagnosis of *herpes zoster* but before its appearance the pain is often confusing *Neuritis* of intercostal nerves without herpes may be confused with pleurisy and sometimes the

pain of pleurisy in which friction is not demonstrated may be wrongly ascribed to neuritis More rarely the pain of *angina pectoris* is confused with that of pleurisy The relation of pain to effort and the presence of other evidence of cardiovascular disease will aid in determining the cardiac origin of the pain The pains of *tabetic crises* which may involve intercostal nerves are intermittent not related to respiration and other neurologic evidences of tabes dorsalis are usually present The pain from pressure on nerves caused by *spondylitis* or a *mediastinal tumor* is often bilateral and usually of long duration In cases of doubt a roentgenogram of the chest and dorsal spine determines the diagnosis *Loud rhonchi* or sonorous rales can be distinguished from a pleural friction rub by their character and by their disappearance on coughing

In the differentiation of diaphragmatic pleurisy from acute inflammatory conditions in the abdomen such as *acute appendicitis* or *acute cholecystitis* the physician is confronted with a difficult problem If in addition to the taking of a careful history the following points are considered few mistakes will be made During diaphragmatic pleurisy (1) the temperature is higher especially if pneumonia is also present than during abdominal inflammation (2) the pain is increased on deep inspiration and the respiratory rate is increased (3) the leukocyte count is usually higher particularly when there is al o pneumonia (4) other evidences of respiratory infection such as cough cyanosis herpes rusty expectoration and signs of consolidation of the lung may be present (5) pressure over the site of pain relieves the discomfort whereas it increases that of an acute abdominal disturbance (6) nausea and vomiting may be present but less constantly than during abdominal inflammations

Prognosis.—The prognosis of acute fibrinous pleurisy depends on the course of the primary or underlying disease with which it is associated In the so called primary cases in which evidences of underlying disease are minimal or absent the outlook is good A considerable number (30 per cent of Lord s eighty two cases) later develop tuberculosis

Treatment.—A patient with acute fibrinous pleurisy should be given a diet of easily digested foods and should remain in bed for a few days after the temperature has become normal Treatment will be determined largely by the requirements of the associated disease as for example in lobar pneumonia The bowels should move daily Most important is treatment to relieve pain In mild cases the local application of a hot water bottle is sufficient in others relief is secured by the application of a mustard plaster In the more severe cases it is necessary to strap the chest with adhesive tape This should be applied tightly during full expiration and should extend past the middle line both in front and back it should not be allowed to remain in place longer than five days During its removal care should be taken to avoid abrasion of the skin this is most easily accomplished by the use of benzine If strapping does not bring relief of the severe pain a hypodermic injection of morphine should be given It is important in all cases for the physician to keep in mind the possibility of the presence or later development of pulmonary tuberculosis Therefore after the disappearance of the pleurisy the patient should be reexamined at stated intervals and subjected to a routine of rest fresh air extra feeding and suitable occupation

ERNEST E IRONS

PLEURISY WITH EFFUSION

Although it is customary to classify pleurisy with effusion as primary or secondary it is doubtful whether the disturbance is ever primary even if the site of other infection cannot be discovered The majority of cases are tuberculous but any type of infection may attack the pleura by direct extension or by metastatic conveyance of organisms from a distant focus Malignant tumors of the lung and pleura both primary and metastatic may cause pleural effusion

Symptoms—Usually serofibrinous pleurisy sets in abruptly with the signs previously described as manifestations of acute fibrinous pleuritis After a few days the pain decreases as the inflamed pleural surfaces become separated by fluid With the appearance of the effusion there may be dyspnea

which increases as the quantity of fluid in creases If the patient is first seen some time after a moderate effusion has occurred dyspnea may be absent and the presence of fluid may be discovered only on physical examination

In the more severe cases the general symptoms may be pronounced The tem perature seldom rises above 102° or 103° F although occasionally it may reach 104° F Except for moderate morning remissions the fever persists until accumulation of the fluid stops the temperature then falls by lysis Chills followed by sweating occasionally occur Digestive disturbances such an ano rexia nausea and vomiting are sometimes present If the attack is prolonged there may be considerable loss of weight and strength

The dyspnea is at times very distressing especially if the fluid accumulates quickly On the other hand it is sometimes aston ishing to find but little disturbance of breathing when the pleural effusion is large, this can probably be accounted for by the slow accumulation of fluid which permits time for compensation by the opposite lung When the effusion is moderate in amount the pulse rate increases moderately perhaps to 100 per minute

There are cases in which none of these symptoms develop and the only subjective evidence of trouble is that the patient does not feel quite normal

Diagnosis —*Inspection* —The posture of the patient is significant He usually lies on the affected side in order to permit freer expansion of the lung on the healthy side When the quantity of effusion is large he may assume a sitting posture The mobility of the affected side is lessened the degree of immobility depending on the amount of effusion The scapula on the affected side is higher than the other and the spine curves toward the diseased side If the effusion is massive the intercostal spaces may be obliterated and the volume of the diseased side of the chest consequently increased In rare instances there is a slight edema of the chest wall Litten s diaphragm phe nomenon is absent The apex beat of the heart is displaced toward the healthy side and in right sided effusions may be as high as the fourth interspace in the midaxillary line In left sided effusions a pulsation may be seen to the right of the sternum this is not due to the apex beat but to movements of the right ventricle The veins of the neck may be distended

Palpation enables the physician to confirm the results of inspection particularly as to the comparative immobility of the affected side and the position of the apex beat When the effusion is large the trachea may be pushed toward the opposite side The normal outward movement of the costal margin on inspiration is absent on the diseased side Tactile fremitus is diminished or absent over the site of the effusion but on account of the proximity of the compressed lung it may be increased above the upper border of the fluid at a still higher level it may be normal As a result of the thickening of the pleura the tactile fremitus may not be restored until long after the absorption of the fluid but it may on the other hand be retained if the lung is consolidated or if bands of adhesions bind the lung to the chest wall When the effusion is on the right side the lower border of the liver may be displaced downward, when on the left side the spleen may be displaced

Percussion over the fluid reveals an in crease in the sense of resistance to the examining fingers The percussion note is flat and high pitched The upper level of the fluid can be determined more readily by light than by heavy percussion The area of flatness corresponds to the area of absent tactile fremitus and in cases of right sided effusion the area of dulness merges with that of the liver in left sided effusion Traube s semilunar space is obliterated When the effusion is moderate in amount the upper limit of dulness is a curve (*Damoiseau s* curve—Ellis s line) which extends upward and laterally from the spine with its highest point in the posterior axillary line from which it curves downward and forward to ward the sternum In some cases the dulness can be shown to be movable when the position of the patient is changed When the effusion is of moderate amount there is an area of tympany above the level of the fluid —the so called skodaic resonance—which is most easily demonstrated below the clav icle This tympanitic note varies in pitch with opening and closing of the mouth (Williams tracheal tone) during inspiration

and expiration (Friedreich s phenomenon), and when the position of the patient is changed (Gerhardt s phenomenon) Strong percussion occasionally elicits a 'cracked pot" sound With massive effusion the area of flatness may extend to the clavicle In the lower back on the healthy side there is a triangular area of dulness with the base below and the apex slightly above the upper level of the fluid (Grocco s triangle) Various explanations of this phenomenon have been given but the present consensus of opinion is that it is due to displacement of the posterior inferior mediastinum by the fluid When the effusion is moderate in amount a triangular area of relative resonance with the base above and the apex below (Garland s triangle) can be demonstrated on the diseased side in the lower back close to the spine This is due to the presence of the compressed lung near the spine and is most evident after the patient has coughed and breathed deeply

Auscultation at the beginning of effusion into the pleural sac sometimes elicits a friction rub which can be heard near the upper limit of the effusion During the process of absorption the friction rub may reappear as the visceral and parietal layers of the pleura come in contact

In cases of pleurisy with effusion the direct method of auscultation is frequently used in studying the breath and voice sounds A comparison of the breath sounds on the two sides often shows that on the healthy side they are exaggerated by a vicarious emphysema while over the site of the effusion they may be distant or absent according to the thickness of the layer of fluid At times bronchial breathing with bronchophony and rales is heard over an effusion especially in children Bronchial breathing is often heard in the interscapular region over the compressed lung Sometimes as the fluid is accumulating a peculiar high pitched nasal quality may characterize the voice sounds near the upper margin of the effusion (egophony) As a rule however the vocal resonance is much diminished indeed diminished breath and voice sounds are two of the most important physical signs of pleurisy with effusion As the fluid is absorbed the breath sounds become louder and vesicular in character

Auscultation of the heart will frequently indicate a change in its position due to the accumulation of fluid in the pleural cavity This displacement can be recognized by a change in the location of the maximal intensity of the heart sounds Often a systolic murmur can be heard over the displaced heart If the lappet of lung over the left cardiac border is involved a pleuropericardial friction rub may be audible

Roentgenoscopy—Roentgenograms often demonstrate small pleural effusions which are not demonstrable by percussion and are of particular value in locating encapsulated

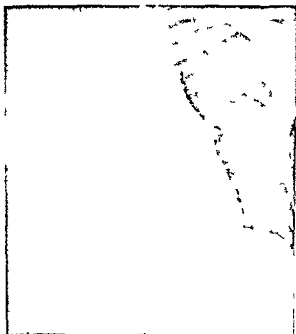

Fig 99—Fluid in right pleural cavity Man thirty four years of age

fluid It is best to expose the films with the patient sitting or standing The fluoroscope offers a ready means of studying the chest in many different positions and reveals the displacements of the heart and mediastinum Roentgenograms taken with the patient lying on the affected side will confirm the presence of small effusions not clearly demonstrable in the upright position

In the majority of cases in which pleural effusion is suspected it is wise to perform an exploratory puncture not only in order to confirm diagnosis but also to obtain the fluid for chemical bacteriologic and cytologic

study The information thus obtained is of value in indicating the primary focus of infection and in determining the type of the invading organism

Diaphragmatic Pleurisy with Effusion—In diaphragmatic pleurisy with effusion the fluid accumulates between the lower borders of the lungs and the diaphragm In general, the symptoms and signs at the onset of the disease are the same as those which accompany the onset of dry diaphragmatic pleurisy In many cases the referred pain in the hypochondrium, the shoulder, or the lumbar region is so marked that there is danger of mistaking the condition for an abdominal lesion

Interlobar Serofibrinous Effusion—The interlobar form of serofibrinous effusion is caused by adhesions which prevent the passage of fluid into the general pleural cavity The characteristic physical signs include some limitation of expansion on the affected side a diminution in tactile fremitus and dulness on percussion over an area which corresponds to an interlobar fissure while above and below this area there may be normal or skodaic resonance The breath sounds are distant over the dull area accompanied perhaps by moist rales As it is often difficult to locate the fluid by exploratory puncture a long needle should be used and the puncture made over the area of dulness keeping in mind the site of the anatomic divisions between the lobes, and avoiding injury to organs and blood vessels Roentgenograms are of great value in detecting interlobar effusions Sometimes an interlobar effusion communicates with a localized effusion in the general pleural cavity thus giving rise to the shirt stud shaped effusion described by Sabourin

Mediastinal Serofibrinous Pleurisy—In mediastinal serofibrinous pleurisy the fluid collects either anteriorly or posteriorly between the mediastinum and the pulmonary pleura The patient often complains of intense pain in the region of the sternum on breathing coughing or swallowing Cyanosis may result from pressure of the effusion on the mediastinal blood vessels Effusions of this type frequently become purulent The area of mediastinal dulness may be widened and a friction rub may be heard to the right of the sternum The diagnosis of this form of pleurisy can best be established by a roentgenogram

Serofibrinous Pleurisy with Polyserositis—When serofibrinous pleurisy is part of a polyserositis there probably will be a pericardial or a peritoneal effusion, or both in addition to the pleural effusion The majority of these cases are tuberculous

Chronic Pleurisy with Effusion—Chronic pleurisy with effusion is comparatively rare and is generally the result of acute effusion which has failed to be absorbed The effusion is frequently pocketed by numerous adhesions Most of the cases are tuberculous With the increase in adhesions' thickening or calcification of the pleura retraction of the chest wall displacement of organs and perhaps the persistence of small pockets of fluid puzzling physical signs may be produced which simulate larger effusions or consolidation of the lung

Differential Diagnosis—With a careful history a painstaking physical examination including a leukocyte count an exploratory puncture and a roentgenogram of the chest the diagnosis of serofibrinous pleuritis can usually be made without much difficulty It is necessary to determine not only the presence of fluid but also its character If the exudate is purulent it is necessary to find the causative organism as the treatment varies according to the type of the invading bacteria for example the treatment of a pneumococcal differs from that of a streptococcal infection

In the differential diagnosis of effusion into the pleural cavity the possibility of one or more of the following conditions must be considered (1) acute lobar pneumonia (2) chronic fibrinous pleuritis, (3) tumors of the lung pleura or mediastinum (4) pericarditis with effusion (5) obstruction or compression of a bronchus (6) pulmonary abscess (7) pathologic conditions below the diaphragm such as abscess of the liver or subdiaphragmatic abscess

Lobar pneumonia is identified by the initial chill high fever rapid respiration and rust colored expectoration as well as by increased tactile fremitus bronchial breathing and bronchophony over the consolidated area Pneumonia does not however always manifest these typical signs Thus if there is a plugging of the bronchus with

mucus or a thick layer of fibrinous exudate over the pleura the tactile fremitus may be absent and the breath sounds distant The *percussion note* over fluid has a flat wooden quality and *offers increased resistance* to the finger It is also difficult to distinguish effusion from pneumonia in cases of high pitched tubular or amphoric breathing Displacement of organs and obliteration of the intercostal spaces are strong evidences of effusion If there is any doubt the physician should make an exploratory puncture with a good sized needle

Chronic fibrinous pleurisy may cause all the signs of a small or moderate effusion but in the former there is no displacement of the heart, or the displacement is toward and not away from the affected side There is little or no elevation of temperature In doubtful cases a fluoroscopic examination of the chest reveals the absence of fluid

Tumors of the lung or pleura may impair the resonance and suppress the breath sounds Absence of fever loss of weight and the discovery of a tumor elsewhere as in the breast or prostate or a history of the previous removal of a tumor often lead to the diagnosis of tumor of the lung or pleura Tumors of the lung can usually be demonstrated by the roentgen ray Tumors of the pleura may be accompanied by an effusion which is frequently bloody and contains a large proportion of endothelial cells As a rule tumors of the mediastinum can be differentiated from mediastinal pleurisy by means of the roentgen ray

It may be difficult to distinguish *pericarditis with effusion* from a left sided pleural effusion The diagnosis of a pericardial effusion is determined by the characteristic shape of the area of cardiac dulness the absence of displacement of the heart intense dyspnea the pericardial friction rub and normal resonance in the axilla between a large area of dulness in front and the area of posterior dulness caused by compression of the lung The latter usually manifests itself in a small area at the angle of the scapula over which the breath sounds are tubular in character

Obstruction of a bronchus by a foreign body or compression by a tumor or aneurysm is evidenced at the base of the lung by the absence of tactile fremitus by impaired resonance and distant or absent breath sounds as well as by the asthmatoid wheeze described by Chevalier Jackson The history the absence of cardiac displacement and a roentgen ray examination of the chest confirm the diagnosis

Patients with subphrenic abscess or other conditions which push up the diaphragm and compress the lungs may manifest signs similar to those of fluid in the pleural cavity Pathologic conditions below the diaphragm do not impair the outward movements of the costal margin from the median line on inspiration The importance of the movements of the costal margin in the differentiation of pathologic conditions below the diaphragm from those above it has been emphasized by Hoover Just as in all other conditions which may obscure the diagnosis of pleurisy with effusion a fluoroscopic examination of the chest and a roentgenogram will aid in establishing the differential diagnosis

Prognosis —The prognosis in serofibrinous pleurisy is fairly good although it is naturally less favorable in patients with active pulmonary tuberculosis Among the 565 cases of pleurisy with effusion collected by Hamman 167 or 29 7 per cent developed pulmonary tuberculosis Unusual sequelae may develop as in the case of a man twenty years old who though showing no signs of active pulmonary tuberculosis developed tuberculous meningitis during the third week of a pleurisy with effusion (Phillips)

Treatment —In the acute stage of serofibrinous pleurisy the patient should be put to bed and given a nutritious and easily digestible diet with extra milk and cream The bowels should move regularly every day If the temperature is high a sponge bath may be given Moderate limitation of fluids and the use of hydragogue cathartics will be of benefit in some cases of pleural effusion but in general the effusion of pleurisy differs from the transudate of passive congestion in that in the former the pleura being inflamed is less permeable and responds less readily to changes in osmotic pressure than does the relatively unchanged pleura in transudates Maintenance of nutrition is more important than efforts to eliminate fluid by limitation of diet and fluids Pleural exudates which have remained sta

tionary in amount for some days are sometimes rapidly absorbed following exploratory puncture Caffeine and theocin may be used for their diuretic action The effectiveness of iodides in promoting absorption has been questioned except in the granulomatous infiltration of syphilis or actinomycosis

Thoracentesis should be performed and the fluid aspirated (1) when the quantity of the effusion is large enough greatly to displace the heart and mediastinum, (2) when the effusion is moderate in amount but has developed so rapidly that the patient is dyspneic and cyanotic and has tachycardia and (3) when the effusion is moderate but fails to be absorbed after two weeks When necessary aspiration should be repeated The site of the puncture should be either in the sixth interspace in the mid axillary line or in the eighth interspace in the scapular line To facilitate the operation the interspaces can be widened by elevation of the arm Some prefer to aspirate the chest with the patient in the recumbent position The *immediate complications* of aspiration may be largely avoided by gentleness the use of sharp instruments adequate local anesthesia and the slow withdrawal of the fluid to an amount not in excess of 1500 cc in an adult

For aspiration a moderate size needle or a small trocar may be used The trocar is less likely to wound the pleura during aspiration but its introduction is often more painful and the outflow of fluid is more likely to be too rapid than when the smaller bore needle is used Negative pressure may be maintained preferably by siphonage by the attachment of a long piece of rubber tubing of small caliber or by the use of a Potain aspirator

The site of puncture is sterilized by application of tincture of iodine or by phenol followed within twenty seconds by alcohol Local anesthesia is obtained by injection of novocain or by ethyl chloride spray which will produce cutaneous anesthesia In introducing the needle the operator should keep close to the upper border of the rib to avoid injuring the intercostal artery Aspiration should be stopped (1) if the patient complains of oppression in the chest (2) if he feels faint, (3) if he complains of severe pain (4) if a paroxysmal cough begins especially when it is accompanied by expectoration of frothy sputum In rare instances sudden death occurs during aspiration probably as the result of a rapid fall in blood pressure produced by irritation of the pleura Capps and Lewis observed that death frequently occurred in dogs subjected to irrigation of the pleura Sudden death has occurred even during an exploratory puncture in some cases the result of air embolism Acute edema of the lungs with albuminous expectoration may develop after the tapping usually when fluid has been removed too rapidly or in too large amount and proves fatal in about 25 per cent of cases This condition is best treated by a hypodermic injection of morphine and atropine sulfate A hypodermic syringe containing this solution should be prepared before beginning the aspiration Occasionally pneumothorax may result from rupture of a vesicle of the lung or from carelessness in technic Subcutaneous emphysema is rare

The best evidence that the fluid is being absorbed and that the patient is recovering is a steady fall in temperature During convalescence all patients should be treated like tuberculous subjects and given rest a nutritious diet and plenty of fresh air If the patient is anemic iron should be given Later he should if possible choose an occupation and climate favorable for the prevention of tuberculous infection

EMPYEMA

(Pleuritis Purulenta)

Etiology —Empyema is seldom if ever a primary infection usually being secondary to an acute pneumonic infection of the lung to pulmonary phthisis to gangrene or abscess of the lung to wounds of the chest wall or to the extension of an infection from the pericardium or abdomen Empyema may also complicate infectious processes in other parts of the body

Symptoms —The symptoms of empyema vary with the disease to which it is secondary In pneumococcal pneumonia the symptoms of pneumonia dominate the picture and the presence of pus may first be

suspected when after an apparent crisis fever and sweats persist, and the patient fails to gain in strength Sometimes the fever and sweating may be slight and the presence of pus may be suspected from physical signs of fluid Persistence of any evidence of in fection such as fever or leukocytosis in a patient convalescent from pneumonia should raise the suspicion of pus in the chest

In the fulminant infections usually strep tococcal which followed influenza measles and septic sore throat during the first World War (1914–1918) pneumonia and acute seropurulent pleural effusions were frequent and are now occasionally met with in local epidemics The symptoms are those of a se vere infection—fever chills tachycardia sweats weakness The temperature ranges from 101° to 103° F and may rise to 104° or 105° F The purulent effusion develops early and rapidly producing dyspnea and cyanosis which may be due in part to coin cident bronchopneumonia There may be an associated purulent mediastinitis

Empyema may follow pulmonary infec tions of less clinical severity and if small in extent and distant from the chest wall may be found only after thorough routine physical examination Suppurative processes in the abdomen especially appendicitis may give rise to empyema the symptoms of which overshadow those of the original cause Cough is often an early and persistent symptom Clubbing of the fingers is occa sionally seen in empyema of long standing There is usually a marked leukocytosis (15 000–50 000) with a relative increase in polymorphonuclear cells Early in empyema following influenza the leukocyte count may be relatively low

Physical Signs —In simple empyema the physical signs are essentially similar to those of pleural effusion The inflammation of lung and pleura incident to pneumonia favors the formation of adhesions which limit the movement of pus and empyema is fre quently found in small pockets so situated as to be difficult of demonstration by per cussion or auscultation One of the most frequent sites is along the interlobar fissure in the right chest In fleshy patients with large chests the physical signs may be ex tremely difficult to demonstrate even when the amount of pus is relatively large Adhe sions between lung and posterior chest wall may further confuse the physical signs in dicative of fluid The empyema suspected by reason of persistent fever and symptoms of sepsis may be just above the diaphragm or in a thin layer along the chest wall or between the lung and mediastinum

Empyema on the left side may pulsate the cardiac impulse being transmitted to the fluid Sometimes there is slight edema of the chest wall over the empyema and fre quently percussion elicits tenderness not found in simple pleural effusion In children the chest wall of the affected side may be more prominent and the interspaces ob literated In cases of long standing the pus may be coughed up or may perforate the chest wall (empyema necessitatis) The latter condition has been mistaken occasion ally for osteomyelitis of a rib

Diagnosis —In pleural effusion the phys ical signs will frequently suffice to indicate the presence of fluid the purulent nature of which is suspected by reason of the signs of persistent infection or sepsis or because of a preceding pneumonia When the history and physical signs are indefinite more dif ficulty is encountered If pus is suspected the exploring needle should be used always with care for asepsis and to avoid injury of organs and tissues The fluoroscope and roentgenogram are of great value and often reveal collections of pus which would other wise be missed It is often desirable to have early and repeated roentgenograms which with the portable machine can be obtained without unduly disturbing the patient On the other hand resort to the roentgen ray as a substitute for careful physical examina tion and study is unfair to the patient and interferes with the acquirement of skill in physical diagnosis

In *subphrenic abscess* the compression of lung by upward displacement of the di aphragm may give physical signs suggestive of empyema Occasionally an abdominal in fection causes both subphrenic abscess and empyema The roentgen ray is of value in making the distinction

Ulcerative endocarditis and *lung abscess* may produce symptoms of fever and sepsis which raise the question of obscure post pneumonic empyema The physical signs of empyema are often erroneously assumed to

be due to *delayed resolution* This mistake may be avoided by the use of the exploring needle and the roentgen ray

In fulminant streptococcal infections of the lung seropurulent effusions may develop rapidly and the dulness and dyspnea are then sometimes wrongly ascribed to extensive pneumonic consolidation rather than to a combination of both In suppurative pericardial effusion the possible persistent pericardial friction rub the outlines of dulness and the roentgenogram will help in distinguishing the condition from empyema

Prognosis—The prognosis in empyema depends on the associated diseases and on the resistance of the individual It is very frequently fatal in children under two years of age (published reports show a mortality varying from 32 to 78 per cent) In children of more than two years the death rate is lower (16 to 26 per cent) For patients of all ages Moschcowitz gives mortality figures which vary from 18 9 to 45 per cent Lord states that of 252 patients in his series 22 2 per cent died in the hospital The use of sulfonamides has reduced the case fatality in children Powers reports twelve cases of streptococcal empyema treated with sulfanilamide and sulfapyridine combined with appropriate surgical procedures with no deaths

The mortality bears a relation not only to age but also to the type of the infection streptococcal infections being more often fatal than those of pneumococcal origin In many cases death should be ascribed to the coexistent pneumonia rather than to the empyema

A neglected empyema may rupture internally into the lung or bronchus or externally through the chest wall More remote results of an untreated empyema may be encountered such as arthritis brain abscess endocarditis and amyloid changes in the liver spleen and kidney

Rare instances have been recorded of perforation of an empyema into other thoracic viscera—trachea esophagus pericardial cavity More remarkable are the perforations of the diaphragm which cause a general peritonitis In even more unusual cases the pus burrows along the spine and psoas muscle to the iliac fossa where it simulates a psoas abscess

Treatment—*The treatment of empyema* varies with the type and virulence of the infection When the quantity of effusion in pneumococcal empyema is small patients occasionally recover completely after aspiration alone Adhesions form early in pneumococcal empyema so that thoracotomy and costectomy can be performed in most cases as soon as the diagnosis is made If however empyema is seen early a *primary aspiration may be advisable* The treatment of pneumococcal and streptococcal pneumonia by sulfonamides has greatly reduced the case fatality but the incidence of complications including empyema has not been correspondingly reduced This may well be due to the survival of the more seriously ill patients who would previously have died Keefer concluded from a study of fifty five cases of streptococcal pneumonia and empyema that the fatality rate in both pneumonia and empyema was reduced by the use of sulfonamide drugs combined with thoracotomy when indicated

In streptococcal empyema adhesions form very slowly Because of this fact and the consequent danger of collapse of the lung because of the danger of infection of the blood stream and because the patient is usually desperately ill, it is wise to aspirate every other day until the pus *becomes thick* and the pneumonia subsides Thoracotomy with resection of a rib should then be performed In these cases it is often difficult to secure adequate drainage as localized pockets are apt to be separated from each other by adhesions These are less likely to develop if aspiration is so frequent *that no* great amount of exudate can accumulate Irrigation of the chest cavity with Dakin s solution has been advocated by some and condemned by others

In old empyema cavities which have persisted in spite of prolonged drainage *resection* of ribs has been employed *allowing* the chest wall to retract with obliteration of the cavity Extensive rib resections have again come into favor in the treatment of tuberculous empyema Each case should be carefully considered before operation is undertaken In cases of pneumococcal as well as streptococcal empyema in *which fever* persists despite adequate drainage as demonstrated by physical and roentgen ray ex

amination search should be made for other sites of infection Coincident ulcerative endocarditis is sometimes found

General measures for the improvement of the strength and nutrition of the patient should be employed in all cases of empyema Fresh air good food and the administration of iron to combat the anemia constitute the chief therapeutic measures Later in convalescence it is important to encourage expansion of the lung by deep breathing or by having the patient blow water from one bottle to another

ERNEST E IRONS

CHRONIC PLEURISY

There are two types of chronic pleurisy (1) chronic pleurisy with effusion and (2) chronic fibrous pleurisy with adhesions (*pleuritis fibrosa*)

Chronic pleurisy with effusion is comparatively rare and is generally considered to be the result of unsuccessful treatment of the acute condition It may be very resistant to treatment because the exudate tends to become pocketed by adhesions Samuel West reports two interesting cases of this type which were finally cured by free incision and drainage In the first the pleural cavity had been aspirated thirty nine times in twelve months in the second the duration of the pleurisy was thirteen months In general however since most cases of chronic pleurisy are of tuberculous origin it is usually wise to avoid incision because of the danger of secondary infection of the tuberculous pleura

Chronic dry pleurisy with adhesions may be a sequel of pleurisy with effusion or may follow an acute fibrinous pleurisy Nearly always even after a mild case of pleurisy the pleura is altered in some degree After pleurisy with effusion there is left between the two pleural surfaces a certain amount of fibrin which undergoes organization with the formation of adhesions between the lung and the ribs or between the lung and the diaphragm These adhesions may be very firm and may even become calcified Subsequent to an empyema that spontaneously drains through the chest wall there may develop very dense adhesions which limit the expansion of the lung or sometimes extensive pulmonary fibrosis with resultant shrinkage of the lung

The only subjective symptoms in these chronic cases are pain after severe exertion and a feeling of limited expansion on the affected side of the chest

Physical Signs—The affected side is smaller than the healthy side and its expansion is limited particularly at the base Litten s diaphragm phenomenon is absent The spine is curved and concave toward the diseased side The shoulder and nipple on the diseased side are lower and the intercostal spaces are narrower than on the healthy side and the outward movement of the costal margin on deep inspiration is limited Tactile fremitus is diminished the percussion note is impaired and the breath sounds are comparatively feeble over the area of pleurisy

An x ray examination of the chest shows thickening of the pleura deformities of the diaphragm and displacement of the heart and mediastinum toward the affected side Calcified areas of the pleura appear as circular or radiating shadows

Treatment—The treatment of chronic pleurisy with adhesions is designed to build up the patient by the usual dietetic and hygienic measures and to improve the breathing capacity by appropriate physical exercises and pulmonary gymnastics If pulmonary tuberculosis is suspected the usual routine for tuberculous patients should be instituted

ERNEST E IRONS

CIRCULATORY DISTURBANCES AFFECTING THE PLEURA

The noninfectious conditions which may cause effusion of fluid in any part of the body may operate within the chest According to the character of the fluid produced—serous fluid blood or chyle—these are classified as *hydrothorax hemothorax* and *chylothorax*

Hydrothorax—*Definition*—The term hydrothorax is used to designate a transudation of serous fluid into the pleural cavities This is most frequently the result of cardiac or renal disease

Etiology—Hydrothorax usually occurs as a manifestation of general anasarca but it may be the result of some local obstruction of the circulation of the blood or lymph produced by the pressure of a tumor or of an enlarged mediastinal or bronchopulmonary gland In some cases hydrothorax may be due to cardiac insufficiency without coexistent general anasarca It may then be bilateral but more frequently it develops only on the right side presumably as the result of pressure on the *vena azygos major* by the dilated right auricle Fetterolf and Landis suggest that cardiac hydrothorax may be due to pressure on the pulmonary veins by the dilated portions of the heart When hydrothorax occurs as a part of the edema of renal disease it is usually bilateral

Symptoms—The only symptom of hydrothorax is dyspnea Fever and pain if present are due to some other cause

Physical Signs—The physical signs of hydrothorax are the same as those of pleural effusion The fluid obtained by puncture shows the general characteristics of a transudate, having a specific gravity below 1 015 and containing very little albumin and few cells It clots slowly and contains only a small amount of fibrin

Treatment—The treatment of hydrothorax consists in aspiration of the fluid if the quantity is sufficient to cause marked dyspnea, and in such general measures as are necessary to relieve the underlying condition

Hemothorax—*Definition*—The term hemothorax signifies an accumulation of blood in the pleural cavity It does not include the accumulations of hemorrhagic fluids which occasionally result from a tuberculous pleurisy malignant disease of the pleura hemorrhagic diathesis or pneumococcus pleuritis

Etiology—Hemothorax is usually due to the rupture of an aneurysm to the erosion of an intercostal vessel by a tumor or necrotic rib or to trauma In the first World War the condition was often produced by gunshot wounds or other injuries of the chest and lungs Effusion following pulmonary infarct while usually serous or only blood stained may be composed largely of blood Hemothorax has been reported following snake bite in India

Symptoms—The symptoms of hemothorax may be divided into two groups (1) those due to the pressure of the rapidly accumulating fluid in the pleural cavity—dyspnea and cough, and (2) those due to anemia from loss of blood—faintness, sweating air hunger, rapid beating of the heart and coldness of the extremities After the first day there is some fever If the lung is wounded there is usually hemoptysis

Physical Signs—The physical signs are those of fluid in the pleural cavity and of secondary anemia Exploratory puncture reveals not only blood but also some serous fluid as the presence of free blood always causes the transudation of a certain amount of serum The coagulability of the blood is below normal probably because some change in the fibrinogen is caused by contact with the endothelium of the pleura During absorption the skin may assume a slight icteric tinge

Complications—Infection of the effused blood is the most serious complication Pneumohemothorax is not uncommon and occasionally develops into pyopneumohemothorax Sometimes the injury may cause pneumonia a pulmonary abscess or gangrene A generalized streptococcus septicemia or septicopyemia may at times result The development of either a localized or a generalized infection is indicated by the usual signs—increasing temperature and pulse rate, chills sweats and such local symptoms as increase of the exudate and persistent cough

Diagnosis—The diagnosis of hemothorax can usually be made from the history and physical signs When signs of an effusion into one pleural cavity develop within a few hours after injury they are usually due to hemothorax An exploratory puncture and a fluoroscopic examination of the chest verify the diagnosis

Prognosis—The prognosis is always serious the mortality varying from 30 to 50 per cent

Treatment—The patient should be kept absolutely at rest External wounds should receive the usual surgical care Immobilization of the involved side with adhesive tape aids in controlling the hemorrhage but aside from this symptomatic treatment is usually employed If there is distress from

pressure a slow aspiration may be performed If the hemorrhage is sufficient to cause alarming symptoms active surgical intervention may be required to stop the bleeding Transfusion of blood may be a life-saving measure when there has been a large loss of blood or in cases of infection If the bloody effusion contains pathogenic organisms free drainage is necessary

Chylothorax — *Definition* — Chylothorax is a term applied to an accumulation of milky fluid in the pleural cavity This may consist of pure chyle or of a chyliform serous effusion containing fat droplets which are not derived from the lymph channels In certain cases the fluid may be milky in appearance without containing fat droplets The milkiness in these cases appears to be due to presence of albuminous bodies the exact nature of which is uncertain Blankenhorn however in his report of seven cases of chylous effusion states that he does not believe that definitely milky fluids have ever been found the turbidity of which was not due to the presence of emulsified fat derived from the chyle

Incidence —Chylothorax is of infrequent occurrence Rotmann in 1896 succeeded in collecting forty nine cases from the literature and comparatively few cases have been reported since that date

Etiology —The presence of *true* chylous fluid in the pleural cavity is due to some injury or obstruction of the thoracic duct by trauma by a new growth in the pleura by enlarged glands or by parasites When the effusion is chyliform the pleural exudate may be due to any of the causes of a serous exudate the chylous appearance being produced by fat droplets which have escaped from the disintegrating endothelial leukocytic or tumor cells

Symptoms and Physical Signs —The symptoms and physical signs are those of a pleural effusion The nature of the fluid can be determined only by puncture In true chylothorax the percentage of fat in the fluid may be as high as 10 per cent and a thick cream forms on the surface of the effusion

Prognosis —The prognosis depends chiefly upon the underlying disease which is usually of a grave nature The danger from the primary cause is increased by the pressure of the pleural exudate Of twenty two patients in Rotmann s series only four recovered Slight lesions of the thoracic duct may heal and the duct remain patent

Treatment.—The only specific treatment of chylothorax consists in repeated aspiration to relieve the symptoms of pressure Strapping the affected side may aid by diminishing the respiratory movements and thus stabilizing the pressure Surgical intervention is rarely of value although Helferich reports recovery in one case after thoracotomy In one case of chylothorax seen by the writer in which there were multiple tumors presumably lymphosarcomata involving the mediastinum and upper abdomen with enlargement of lymph nodes in the neck and groins the fluid as well as the tumors disappeared following roentgen ray treatment Fourteen years later after thirteen years of good health the patient died of carcinoma of the urinary bladder with metastases in the regional lymph nodes and liver The receptaculum chyli and thoracic duct were surrounded and moderately constricted by scar tissue without local evidence of tumor

Ernest E Irons

PNEUMOTHORAX

Definition —Pneumothorax is a condition characterized by the presence of atmospheric air or of gas in the pleural cavity Air is rarely present alone but is generally associated with a serous effusion (hydropneumothorax) or a purulent effusion (pyopneumothorax)

Various terms are employed to describe the manner in which the air or gas enters the pleural cavity Thus when air enters through the chest wall as for example after a pleural tapping the condition is called *external pneumothorax* when gas enters the pleural cavity as the result of a rupture of the lung *internal pneumothorax* is the term employed The condition in which the perforation in the wall of the pleural cavity is patent during both inspiration and expiration is known as *open pneumothorax* that in which the opening is closed during both inspiration and expiration *closed pneumothorax* When the perforation is patent during inspiration but wholly or partially closed

during expiration the condition is called *valvular pneumothorax*

History — Although Hippocrates noted the succussion splash he failed to distinguish between empyema and pneumothorax Hewson (1739–1774) observed the presence of air in the pleural cavity and in 1803 Itard recognized the relation of pneumothorax to tuberculosis In 1819 Laennec gave such a thorough description of the symptoms and physical signs of pneumothorax that little has been added up to the present time Forlanini (1895) suggested the use of artificial pneumothorax in the treatment of tuberculosis and since then there has been increased interest in the subject

Etiology — In considering the probable etiology of spontaneous pneumothorax, regard must be had for preexisting pulmonary disease In patients with preexisting pulmonary tuberculosis the usual cause of pneumothorax is caseous ulceration of the pleura Such cases are usually complicated by serous or purulent effusion

Spontaneous pneumothorax in persons previously in apparently good health is not usually associated with active tuberculosis although in some of these the primary lesion may have been a healed tubercle which gave rise to pleural adhesions Of forty six cases followed for two years or more only one was proved to have active tuberculosis (Amberson) The cause of the pneumothorax in this group is believed to be rupture of emphysematous blebs of the pleura or the tear of adhesions Rupture of a bulla in bullous emphysema and the rupture of the mediastinal tissue into the pleural space in mediastinal emphysema have given rise to spontaneous pneumothorax In several cases of streptothrix infection of the lung in which collapse had occurred bullae which projected out from the pleura were easily visible on the x ray film in the area of pneumothorax (H E Potter) Pneumothorax has been noted as a complication of anthracosilicosis in miners Of 199 cases of uncomplicated anthracosilicosis there were seven cases of pneumothorax (3 5 per cent) while in 307 cases complicated by active tuberculosis there were fourteen cases (4 5 per cent) (Sokoloff and Farrell) Coincident emphysema pleural adhesions and severe cough were believed to be contributing factors

Pneumothorax occurs less frequently as a complication of pulmonary gangrene abscess or infarction or other diseases which cause perforation of the visceral pleura such as tumors or echinococcus disease Extrapulmonary causes are subphrenic abscess and lesions giving rise to suppurative processes or erosions of tissue such as tumors and ulcerations of the esophagus and stomach Pneumothorax results also from perforating wounds of the chest and from thoracentesis

Morbid Physiology — Normally the elastic tension of the lungs produces a negative pressure within the pleural cavity which is greater during inspiration than during expiration In thirty six observations Aron found that the maximum pressure during quiet inspiration was —5 09 mm of mercury and the minimum for quiet expiration —2.54 mm of mercury Because of this negative pressure the admission of air into the pleural cavity on one side causes the lung on that side to retract and the heart and mediastinum to be displaced toward the healthy side where the pleura is still under negative pressure In open pneumothorax the external pressure is equal to the internal pressure and consequently respiration is ineffective In closed pneumothorax the internal pressure is increased particularly as soon as effusion occurs Asphyxia may be caused by either open or closed pneumothorax but more frequently by the former In valvular pneumothorax the air enters the pleural cavity during inspiration but cannot escape during expiration and in consequence the intrapleural tension becomes greatly increased and dangerously interferes with the circulation Lord reports that in one case of valvular pneumothorax the average intrapleural pressure was +7 93 mm of mercury at the height of inspiration and +10 48 mm of mercury during expiration In these cases there is a compensatory emphysema of the healthy lung

Symptoms — The onset of pneumothorax is sudden and without any apparent cause The patient is suddenly seized with a sharp, stabbing tearing *pain* in the side of the chest as if something had suddenly given way The pain is usually felt in the mid axillary region but may be referred to the scapula or beneath the clavicle or may radiate around the chest As a rule it is of short duration Accompanying the pain is a *shortness of breath* which steadily increases The

patient is usually found sitting up in bed in great distress with a pale face bathed in perspiration and with cold extremities The *mental distress* is extreme as the patient feels that he is about to die The dyspnea may be so severe that it is necessary to insert a needle into the side in order to allow the air to escape if the air reaccumulates rapidly it may be necessary to repeat the puncture several times Some patients die in spite of repeated tappings in others the dyspnea gradually becomes less severe and the urgency of the symptoms disappears

The severity of symptoms especially of dyspnea depends as in pleural effusion on the rate of accumulation as well as on the amount of air or of fluid in the chest When the pneumothorax develops slowly dyspnea may be absent while the patient is at rest In one case in a young man the condition was discovered by reason of dyspnea on swimming The left lung was almost entirely collapsed yet he had no dyspnea on walking There was no fever effusion or evidence of tuberculosis and when examined one year later the chest was normal

Physical Signs—On inspection the affected side is seen to be greatly distended the shoulder raised and the intercostal spaces widened The respiratory excursion is very slight with no outward movement of the costal margin on deep inspiration The superficial veins are sometimes dilated and there may be slight general edema of the whole side of the chest The heart is displaced toward *the unaffected side and its* impulse may be seen in the new position The patient usually assumes a sitting or half sitting position In Garde s remarkable case the knee-chest position was assumed

Palpation confirms the results of inspection Tactile fremitus on the affected side if felt at all is indistinct in the majority of cases it is entirely absent In right sided pneumothorax the right lobe of the liver may be displaced downward The larynx and trachea may be shifted toward the healthy side If an effusion has developed a splashing ound may be audible when the patient is shaken (Hippocratic succussion splash) Sometimes this can be heard at quite a distance and often can be voluntarily produced by the patient

The *percussion note* varies with the tension of the gas in the pleural cavity, the position of the retracted lung the presence of adhesions the character of the pneumothorax—whether open or closed—and the amount of fluid in the pleural cavity It may vary in quality from tympany to dulness Usually the note is hyperresonant, and if the pneumothorax is large the hyperresonance may extend beyond the limits of the normal lung Occasionally a cracked pot' sound may be obtained which is caused either by the proximity of a pulmonary cavity to the chest wall or by the communication of a large open fistula with the pleural cavity If fluid or pus is present percussion over the lower portion of the pleural cavity elicits a dull or flat tone and a dull area is demarcated from the resonant area by a horizontal line which is in contrast to the curved upper limit of dulness in pleural effusion without air

In most cases *auscultation* shows the breath sounds to be greatly diminished on the affected side and exaggerated on the healthy side This contrast and the hyperresonant percussion note are usually the first signs that lead to suspicion of pneumothorax If an open fistula exists the breath sounds may be amphoric in character and a gurgling sound (the so-called water whistle murmur) may be produced The whispered and spoken voice sounds are decreased Often at the end of inspiration there is a peculiar metallic tinkle comparable to that produced by striking a glass vessel with *a pin This is thought to be due to the bursting* of bubbles of air which have risen to the surface of the fluid from a submerged fistula or to the falling of drops from the walls of the cavity to the surface of the fluid below The coin sound produced by the tapping of one coin with another on the anterior part of the chest while the examiner listens posteriorly is very characteristic It is a ringing metallic sound quite unlike the normal resonance of the healthy lung

Gas Analysis—In experiments on dogs Emerson found that when air is introduced into the pleural cavity the nitrogen content remains constant but the oxygen content quickly diminishes and there is a rapid accumulation of carbon dioxide If the amount of oxygen remains normal the presence of an open fistula is suggested Air is quite

rapidly absorbed from the normal pleural cavity—in most cases within about a week—but when the pleura is diseased the process may take several weeks

A *roentgen-ray examination* of the chest should be made when pneumothorax is suspected The characteristic roentgenographic signs of pneumothorax are abnormal clearness of the affected side absence of the normal lung markings, retraction of the lung displacement of the heart and mediastinum depression of the diaphragm and the horizontal level of the fluid if present If

Fig 100—Total spontaneous collapse (pneumothorax) of the right lung Man forty years of age (A) Collapsed lobes of lung (B) Bleb inflated with air (C) Fluid level within the bleb Subsequent recovery with complete expansion of the lung The outlines of the bleb still could be seen in the x ray film (Courtesy H E Potter)

the patient is shaken waves in the fluid may be observed A *fluoroscopic examination* may show the so called paradoxic contraction of the diaphragm, the diaphragm moving upward on inspiration and downward on expiration

Diagnosis—The recognition of pneumothorax as a rule presents no great difficulty if the possibility of its existence has occurred to the physician The history of a sudden onset of pain and dyspnea, immobility of the affected side with diminished tactile fremitus hyperresonance decrease of the breath sounds displacement of the heart and mediastinum and the presence of the coin sound all indicate pneumothorax

In the *differential diagnosis* one must consider (1) the presence of a large pulmonary cavity (2) subphrenic pyopneumothorax, (3) diaphragmatic hernia, (4) gaseous distention of the stomach and (5) pleurisy with effusion

Pulmonary cavities are seldom large enough to make difficult their differentiation from pneumothorax An enormous cavity might be mistaken for pneumothorax, for the percussion and auscultatory signs could be the same but the onset of cavitation is not sudden and there is no displacement of the heart or mediastinum A roentgenogram will also demonstrate that the diaphragm is elevated rather than depressed

The differentiation of *subphrenic pyopneumothorax* may be very difficult The history will usually indicate the presence of some abdominal lesion such as perforation of a gastric or duodenal ulcer or of the appendix The liver is depressed and the lower portion of the lung compressed There may be resonance or tympany above the level of the compressed lung and movable dullness below with amphoric or diminished respiratory murmur metallic tinkle coin sound and succussion splash The mobility of the chest is not interfered with so much as in pneumothorax and the costal margin on the affected side may move outward The heart is only slightly displaced Roentgenograms show that the diaphragm is pushed upward and that there is a relatively clear space in the costophrenic angle The pus obtained by puncture often has a fecal odor In many cases jaundice is present

Diaphragmatic hernia provides a history of trauma with attacks of colic nausea and vomiting If a barium meal is given the condition can be readily diagnosed

Gaseous distention of the stomach can be easily determined by the passage of a stomach tube or by x ray examination

In *pleurisy with effusion* even though there may be amphoric breathing the succussion splash metallic tinkle and coin sounds are absent

To differentiate surely between hydro and pyopneumothorax an exploratory puncture is necessary

Prognosis—The course and prognosis of

pneumothorax depend to a large extent on the underlying cause The majority of patients die within the first few days Of West s thirty nine patients ten died within twenty four hours eighteen during the first week and the total mortality for seventy four cases was 70 per cent Death during the first day is due either to circulatory embarrassment or to suffocation from a sudden discharge of the contents of the cavity into the bronchi When death occurs later it may be due to the effusion which follows the pneumothorax In other cases death is caused by the original disease which is often tuberculosis Spontaneous pneumothorax of nontuberculous origin is rarely fatal and complete recovery is frequent In one patient repeated recurrences of pneumothorax were noted Fussell and Riesman report only one death among fifty eight cases

Treatment —Absolute rest should be assured and the cough controlled by the administration of morphine The affected side can be immobilized by strapping and the patient should be instructed to avoid deep breathing and coughing if possible

Patients usually recover from spontaneous valvular pneumothorax if left alone but when the respiration and the circulation are greatly embarrassed aspiration should be performed at once to relieve the intrapleural pressure and repeated as often as necessary When the condition is not so urgent it is well to avoid aspiration as long as possible to allow the fistula to close especially in cases of serous effusion when the aspiration should be delayed for two weeks if possible The same plan may be followed in the treatment of pyopneumothorax unless the symptoms of sepsis are too severe If removal of the exudate is indicated aspiration should be followed by resection of a rib and drainage

ERNEST E IRONS

PARASITIC AND OTHER INVASIONS OF THE PLEURA

Echinococcus disease of the pleura is very rare in this country The right pleural cavity is more frequently affected The symptoms often resemble those produced by a slow growing intrathoracic tumor Dyspnea increases progressively Fever is absent but emaciation is common The physical signs are those due to encysted pleural fluid There may be echinococcus cysts elsewhere in the body The blood shows eosinophilia Urticaria is often present In addition to the complement fixation and precipitation tests a skin test using fluid from echinococcus cysts is of value in diagnosis The *treatment* is surgical

In rare instances the pleura may be invaded by *Actinomyces bovis* and by *streptothrix* which produce very similar clinical and pathologic pictures In *actinomycosis* the pleural infection may be an extension from the neck the esophagus or the abdominal cavity Erosion of the ribs and perforation of the chest wall are common features The diagnosis can be established by the presence of granules with branching gram positive filaments and radially disposed club shaped eosin staining bodies The prognosis is grave *Treatment* consists in a combination of the internal administration of potassium iodide and surgical measures

In *streptothricosis of the pleura* the infection is an extension from the lung Clinically the condition resembles tuberculosis There may be multiple pulmonary abscesses The presence of threadlike branching organisms which to a considerable degree resist decolorization with acid and alcohol establishes the diagnosis

ERNEST E IRONS

TUMORS OF THE PLEURA

Tumors of the pleura may be either benign or malignant Benign tumors are extremely rare although lipoma fibroma osteoma angioma and xanthoma of the pleura have been described The lipomata arise either from the subpleural fatty tissue or from the fatty tissue of the thoracic wall

Primary malignant tumors—carcinoma sarcoma and endothelioma—are of rare occurrence metastases from primary new growths in the breasts lungs stomach esophagus or thymus are much more common

Symptoms and Physical Signs —The symptoms and physical signs of malignant pleural tumors somewhat resemble those of pleurisy with effusion As a rule fever is

absent Loss of weight and strength and emaciation are usually marked and there is a progressive secondary anemia The fluid *obtained by* tapping may be straw colored but is not infrequently bloody and has a specific gravity of less than 1 018 It contains a larger proportion of endothelial cells and fewer lymphocytes than the ordinary transudate The presence in the pleural exudate of rosettes of cells or of cells showing mitosis is thought to be pathognomonic of malignant disease of the pleura

Prognosis—The disease as a rule terminates fatally within six months though in some cases death may not ensue for twelve or eighteen months

Treatment—The treatment is symptomatic Aspiration should be performed if the dyspnea is urgent Morphine should be administered to relieve pain or distress There is some evidence that life may be prolonged by the use of radium or by x ray therapy

DISEASES OF THE MEDIASTINUM

AFFECTIONS of the mediastinum which should be considered as separate entities distinct from the diseases of certain structures within the mediastinum may be divided into two main groups (1) those involving the connective tissue of the mediastinum including acute and chronic mediastinitis mediastinal abscesses mediastinal hemorrhage and mediastinal emphysema and (2) tumors of the mediastinum

Mediastinitis—*Simple mediastinitis* without suppuration may be associated with pericarditis pleurisy pneumonia or syphilis The subjective symptoms are fever pain beneath the sternum and occasionally cough Physical examination reveals no positive changes Crepitations may be heard along the border of the sternum and the area of mediastinal dulness may be somewhat increased The course of the disease is usually comparatively short but the simple form may become suppurative Enlargement of mediastinal lymph nodes as shown in roentgen films is frequent after acute upper respiratory and pulmonary infections In children especially asthmatic symptoms may result from pressure of the glandular masses on the bronchi

Indurative Mediastinitis—In some cases acute mediastinitis is followed by a great increase in the fibrous tissue—indurative mediastinitis—with adhesions and compression of the great vessels Cyanosis dyspnea and cough are the prominent symptoms The superficial veins are enlarged and the mediastinum broadened as may be shown by x ray and by percussion Often a creaking friction rub may be heard There may be associated adherent pericardium When the thoracic duct is compressed or injured fluid if present in the pleura or peritoneum may be chylous

Suppurative Mediastinitis—Some cases are due to a general infection such as erysipelas and pyemia or mediastinal infections may be an extension from an inflammation of the lung or pleural cavity especially during epidemics of influenza and other respiratory diseases The influenza epidemic of 1917 and 1918 furnished many instances of suppurative mediastinitis frequently associated with empyema

The *chief symptoms* of suppurative mediastinitis are fever which tends to be septic in type sweating local pains and a gradually increasing shortness of breath There may be marked symptoms of pressure As the disease progresses there is anemia and wasting The majority of these cases are fatal though in some instances when the pus makes its way to the surface there is ultimate recovery Should the abscess rupture into the trachea or bronchus a large quantity of pus may be coughed up or death may speedily result from suffocation

Tuberculous Mediastinitis—Tuberculosis may involve any of the groups of mediastinal glands but the tracheal and bronchial glands are those most frequently affected Involvement of the intrathoracic glands usually results from the extension of an infec

tion from the neighboring structures especially from the lung or the pleura and occasionally from bone The tuberculous process may extend directly from the glands of the neck or along the lymphatics through the diaphragm to those in the abdomen This condition sometimes follows an acute infection such as whooping cough It is more common in children than in adults That in children enlargements of the tracheobronchial glands are frequently not tuberculous must however be kept in mind as these glands are always enlarged in acute bronchial infections in children and also in so called glandular fever The glands have a tendency to become caseous then purulent thus being a common origin of chronic abscesses within the mediastinum They may perforate into the aorta or pulmonary artery and cause fatal hemorrhage or they may ulcerate into the trachea or into the thoracic duct and thus sometimes cause acute miliary tuberculosis

Symptoms—The symptoms of tuberculous mediastinitis are fever wasting anemia night sweats loss of appetite more or less disturbance in breathing which sometimes simulates spasmodic asthma and coughing which may be spasmodic and croupy in quality or may occur in paroxysms resembling those of whooping cough If the glands should rupture into the trachea the patient may cough up purulent or caseous material In some chronic cases even calcareous fragments (lung stones) may be expectorated Physical examination discloses marked dullness over the sternum particularly when the anterior mediastinal glands are tuberculous Eustace Smith has described in children a venous hum which is audible at the root of the neck when the head is thrown back This he attributes to pressure of the enlarged glands on the venous trunks Whispered bronchophony below the level of the fourth dorsal vertebra usually more marked on the right side than on the left suggests enlargement of the bronchial glands (D Espine s sign) Since these signs are to a certain extent identical with those produced by a small cavity or by certain pleuritic conditions their significance should be established by roentgenograms of the chest which disclose the presence of enlarged glands

Treatment—The treatment of *simple mediastinitis* consists of rest in bed local applications of heat to the sternum and the administration of codeine or morphine to relieve the cough If the disease passes into the *chronic* or *indurative* stage and is associated with adherence of the pericardium and cardiac dilatation digitalis should be given to support the heart In any case the general treatment should be adapted to the underlying condition Thus if the mediastinitis is syphilitic in origin antisyphilitic treatment with mercury and potassium iodide should be given In tuberculous mediastinitis the usual hygienic measures—rest fresh air and extra nourishment—are indicated In chronic suppurative mediastinitis if the symptoms of pressure are not severe an expectant policy may be justified as the pus may burrow toward the surface If the process is acute prompt surgical measures may be required The search for pus is usually difficult however and even if successful rarely saves the patient s life

Mediastinal Hemorrhage —Mediastinal hemorrhage is most frequently due to perforation of the aorta or one of its branches and is rarely recognized during life Trauma resulting in fracture of the sternum or in injuries of adjacent structures may cause mediastinal hemorrhage

Mediastinal Emphysema —Mediastinal emphysema may occasionally result from inflammations in the mediastinum the air gaining access to the mediastinum through a perforation of the trachea or a bronchus or making its way from the neck beneath the deep cervical fascia In some instances the air may extend through the cellular tissue of the neck or even over the front of the chest and give rise to an extensive subcutaneous emphysema The subcutaneous emphysema seen in influenza in 1917 and 1918 originated in the mediastinum and was believed to have been initiated by the rupture of air vesicles near the hilum of the lung and thence to have extended along the interstitial tissue upward into the cervical fascia

True mediastinal emphysema should be differentiated from the so-called *subfascial* or *false mediastinal emphysema* which sometimes results from artificial pneumothorax

The evidences of mediastinal emphysema

are subcutaneous emphysema in the neck and dyspnea if there is great pressure The *physical signs* are a high tympanitic percussion note over the mediastinum and in some cases obliteration of the heart dulness Auscultation may elicit crepitation and distant heart sounds or the latter may be inaudible The x ray film may show air in the mediastinum Hamman has described a peculiar crunching murmur along the left border of the heart synchronous with the heart beat

Treatment should be directed to the underlying cause of the emphysema

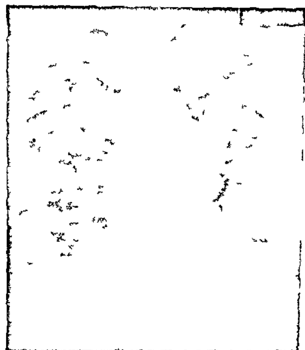

Fig 101—Mediastinal tumor calcified rings Man fifty-eight years of age Slow growth over four years Progressive atelectasis at base of left lung The relatively benign course following x ray therapy and the rounded edges of the tumor suggest that this was not carcinoma but rather a lymphosarcoma or dermoid

Tumors of the Mediastinum—These may be primary or secondary malignant or benign Benign tumors are comparatively rare although fibroma lipoma chondroma myoma intrathoracic adenoma or cyst adenoma of the thyroid simple echinococcus and dermoid cysts have been described

Various forms of *sarcoma* comprise the group of primary tumors which develop most frequently in the mediastinum They are usually primary growths originating in the loose connective tissue of the mediastinum in the peribronchial and mediastinal lymph nodes and in the thymus Secondary sarcoma of the mediastinum may follow sarcoma in the arm leg or other parts of the body while, on the other hand primary mediastinal sarcoma *may be followed by* the development of metastatic nodules in the liver spleen and kidneys

Mediastinal carcinoma is usually secondary to carcinoma elsewhere (for instance in the breast or gastro intestinal tract) but in rare cases is primary

The majority of tumors of the mediastinum develop in patients between thirty and fifty years of age

Symptoms—In considering the symptoms and physical signs caused by mediastinal tumors it is important to have in mind the anatomic structures within the mediastinum which may be compressed These include the superior and inferior vena cava and vena azygos major the aorta and its branches the pulmonary artery, the trachea and bronchi the esophagus, the thoracic duct the heart and pericardium the vagus sympathetic and phrenic nerves the vertebral column and the sternum

The outstanding symptoms are pain or distress disturbance in respiration cough and dysphagia The *pain* which may be constant varies from a feeling of pressure to a burning sensation with periods of acute exacerbation The *respiratory disturbances* vary from a steady progressive shortness of breath to a well defined inspiratory stridor which is often accompanied by wheezing Sometimes, especially in intrathoracic goiter there may be very severe attacks of *suffocation because of the incarceration of the goiter in the superior strait* In one patient *persistent nausea* was relieved by the removal of a large substernal goiter *Cyanosis is often present* When there is profuse pleuritic effusion the patients are *often obliged to maintain the sitting posture* or at times the knee chest position An enormous mediastinal lipoma described by Leopold weighed 17 pounds 6 ounces (7 9 Kg) *The cough* may be paroxysmal but in many cases is the expression *of a constant effort* on the part of the patient to relieve the feeling of obstruction *It frequently* has a curious resounding character—the so called gander" cough The expectoration as a rule is

small in quantity and consists of thin viscid mucus at times however it is profuse mucopurulent or purulent and if the tumor is a dermoid cyst may contain hairs or other characteristic structures The expectoration is often streaked with blood If the tumor invades the trachea there may be profuse hemoptysis

The *dysphagia* is usually due to the pressure of the tumor upon the esophagus, and as the obstruction progresses a pouch like dilatation of the esophagus may form and cause regurgitation of food

In addition to the above symptoms *palpitation* and other cardiac disturbances may be caused by pressure on the heart there may be anginal attacks and inequalities in the radial or the carotid pulse Pressure from the tumor may produce an erosion of the aorta with resultant hemorrhage Venous obstruction may cause an extensive venous thrombosis accompanied by enormous distention of the veins of the upper part of the chest and neck particularly in the rare cases of thrombosis of the superior vena cava The larynx may be fixed so that it no longer ascends and descends with respiration and deglutition The heart may be displaced The aorta and trachea may be surrounded by tumor so that pulsation of the aorta is transmitted to the trachea (tracheal tug)

The principal signs of the presence of a mediastinal tumor elicited by a *physical examination* are a bulging of the chest wall and distention of the veins Sometimes there may be an abnormal pulsation and when the tumor extends above the upper border of the manubrium sterni it can be both seen and palpated There may be cyanosis and swelling of the face neck and upper extremities

In general the physical signs revealed by percussion auscultation or palpation obviously depend upon the position and size of the tumor and the structures to which it is adjacent *Percussion* reveals a widening of the mediastinal area of dulness and if there is obstruction of a bronchus or an accompanying pleural effusion this dulness or flatness may be observed on the affected side of the chest The *auscultatory signs* vary a great deal in different cases When a tumor is situated in the superior mediastinum the quality of the breath sounds may be intensely tubular or amphoric If the trachea is partially obstructed the breath sounds may be feeble throughout both sides of the chest but accompanied by stridor At times a pleuritic friction rub may be heard in the region of the tumor If fluid is present in the pleural cavity the usual signs of pleurisy with effusion are present

Differential Diagnosis.—In the differential diagnosis a careful history and physical examination are of prime importance Of particular significance is the presence of tumors elsewhere or the history of a previous operation for tumor A *fluoroscopic examination* is of value in the final establishment of the diagnosis provided the observations are carefully correlated with the physical findings and the history The mediastinal space should be viewed from different angles and the position of the trachea should be carefully observed as any abnormal variation indicates a displacement of the mediastinal contents

It may be difficult to distinguish a mediastinal abscess from a tumor but when the mediastinal abscess has developed from disease of the vertebrae it usually assumes a fusiform shape gradually tapering off toward the diaphragm In Hodgkin s disease there are often large discrete shadows which correspond to the individual glands and the same is true of leukemia In the latter case blood examination assists in the diagnosis An esophageal diverticulum can usually be readily distinguished from a tumor by means of a fluoroscopic examination after barium has been given by mouth

The differentiation between aneurysm of the aorta and tumor of the mediastinum is of special importance While such time honored signs as expansile pulsation and tracheal tug are suggestive of aneurysm it should be remembered that tumors may rarely pulsate or by their growth about trachea and aorta cause transmission of aortic impulse The fluoroscope and x ray film are of great value in demonstrating the course and size of the aorta

A *laryngoscopic examination* often gives the first clue to the presence of mediastinal pressure by disclosing a paralysis of one of the vocal cords or evidences of compression of the trachea

Laboratory examinations may also be of service For instance when a mediastinal tumor is associated with enlargement of the glands in the supraclavicular space it is often easy to remove one of these glands for histologic examination which may indicate the diagnosis Blood counts are of value particularly in cases of leukemia The examination of the sputum in cases with profuse expectoration or with hemoptysis is of value in differentiating the condition from tuberculosis The finding of teeth and hair in the sputum serves to clinch the diagnosis of the rare dermoid cysts

In general it should be emphasized that the establishment of the diagnosis of a mediastinal tumor should not depend upon any one method but that every diagnostic measure available should be employed the final diagnosis resting upon the correlation of all the findings

Treatment—With the exception of intrathoracic goiters and some dermoid cysts mediastinal tumors can rarely be removed by operation

Fibroid tumors occasionally yield to radiation The growth of carcinomata may be retarded but as tumors of this type are usually metastatic even if the mediastinal tumor is controlled the measure is but palliative and other metastases will almost certainly develop On the other hand the radiation of lymphosarcomata yields quite favorable results these tumors are reduced in size and occasionally permanent benefit is secured

The local involvement of the glands in Hodgkin s disease and in lymphatic leukemia yields readily to radiation but the improvement is temporary

DISEASES OF THE DIAPHRAGM

THE *diaphragm* bears an important relation to the function of respiration and of circulation It is subject to injuries and diseases just as are structures elsewhere in the body although usually the diaphragm is involved as part of a systemic disease or by extension of disease from neighboring organs and tissues Disturbance of the action of the diaphragm by interference with its nerve supply, or by change in the balance of muscle pull as compared with that of other muscles of respiration results in symptoms of great diagnostic importance Normally because of its arch the diaphragm contracts at a disadvantage and therefore the intercostal muscles gain mastery over it the costal margins moving outward during inspiration When the arch of the diaphragm is depressed however as in emphysema or in pleurisy with effusion it contracts to greater advantage and the costal margins are restricted or move toward the median line The nerve supply of the periphery of the diaphragm is derived from the lower six thoracic nerves and pain caused by irritation of this portion is referred to the lower chest the epigastrium and abdominal wall The central portion of the diaphragm is supplied by the phrenic nerve and pain is referred to the neck and trapezius ridge through the fourth cervical nerve

Inflammation of the Diaphragm—Primary inflammation of the diaphragm is rare but on account of the rich blood and lymphatic supply infection readily extends to it from neighboring organs or a generalized infection may become localized The possibilities of the latter occurrence have been especially studied by MacCallum The muscle of the diaphragm appears to be a favorite site for the lodgment of trichinae a fact which explains the troublesome dyspnea sometimes associated with trichinosis

The pleural covering of the diaphragm is frequently invaded by the agent which causes any generalized or localized pleurisy (diaphragmatic pleurisy)

Symptoms—The chief symptoms of diaphragmatic inflammation are dyspnea a feeling of soreness and a sense of pressure over the lower part of the chest hiccup and pain which is referred to the abdomen

and neck as in diaphragmatic pleurisy The chief physical signs are absence of Litten s sign restriction of motion of the lower part of the chest soreness on pressure suppression of breath sounds at the base of the lung and sometimes the presence of superficial rales along the line of attachment of the diaphragm Fluoroscopic examination of the chest shows decreased mobility of the diaphragm

Prognosis—The prognosis depends on that of the underlying condition

Treatment—The patient should be kept at rest The local application of heat and a binder around the lower part of the chest will relieve the symptoms If the pain is severe it may be relieved by the administration of acetylsalicylic acid codeine or morphine

Spasm of the Diaphragm—Spasms of the diaphragm may be either tonic or clonic in character the latter being much more common and much less serious than the former

The most common form of *clonic spasm* is that known as hiccup Clonic spasms with or without hiccup may be associated with diaphragmatic pleurisy or with any acute inflammatory condition within the abdominal cavity In some cases however the source of irritation is in the central nervous system as in brain tumor apoplexy or encephalitis In many cases the spasms are due to indigestion They are not infrequent in influenza In acute abdominal conditions because of the violent disturbance of the neighboring viscera such spasms of the diaphragm are often of serious import

Tonic spasms of the diaphragm are usually symptomatic of a general condition such as epilepsy tetanus strychnine poisoning or eclampsia they may occur in hydrophobia and in rare instances have been associated with asthma The spasm may be short or prolonged the outstanding symptom dyspnea being intensified accordingly If of long duration and associated with spasm of the intercostal muscles the patient dies of asphyxia

Treatment—*Clonic spasms* of the diaphragm may be relieved by inhalations of ammonia by traction on the tongue or compression of the chest by bromides or in severe cases by morphine Inhalation of carbon dioxide has benefited some cases Hiccup due to indigestion is best relieved by frequent feedings of milk or of milk and cream alternating with the administration of alkalis

Tonic spasms may sometimes be stopped by the application of vigorous counterirritation over the regions of diaphragmatic attachment—the epigastrium the thoracic walls the lumbar region Hot compresses and cupping may prove of value or electric stimulation of the diaphragmatic areas The usual antispasmodics such as chloroform ether and bromides may be employed

Paralysis of the Diaphragm.—The phrenic nerve in its course or at its origin in the cervical cord may be involved in diphtheria in poliomyelitis or in inflammatory conditions of the lungs or pleurae it may be contused by injuries or be pressed upon by tumors or by hemorrhages with resulting paralysis of the diaphragm The paralysis may be unilateral or bilateral the latter being very serious Section of the phrenic nerve is sometimes employed to reduce movements of the lung in pulmonary tuberculosis

Signs and Symptoms—Fowler has described the signs and symptoms of paralysis of the diaphragm as follows (1) reversal of the respiratory movements of the epigastrium and hypochondria with recession rather than bulging in these regions during inspiration (2) absence of the downward movements of the abdominal viscera during inspiration (3) increased outward movement of the lower ribs during inspiration (4) dyspnea on exertion or excitement (5) alteration in the voice and cough (6) loss of the compressive action of the abdominal muscles on the viscera during defecation (7) feebleness of expiration and of such reflex expiratory acts as coughing and sneezing (8) diminution of the total capacity of the thorax as the result of increased arching of the diaphragm The last condition as well as the partial or complete immobility of the diaphragm can be demonstrated by fluoroscopic examination

Prognosis—The prognosis is grave varying directly with the extent of the paralysis When the paralysis is complete fatal asphyxia may follow even the slightest exertion

Treatment should be directed toward improving the condition to which the paralysis is primarily due In some cases the local application of electricity may be of value

Diaphragmatic Hernia —The term diaphragmatic hernia indicates the escape of any abdominal organ through the diaphragm into the chest cavity Three types are distinguished (1) *congenital* due to arrest of fetal development which leaves a defect *in the diaphragm so that organs or tissues* normally placed in the abdomen enter the chest This condition is usually met with in infants many of whom die within a few days after birth In some cases if the condition is not incompatible with life and growth the subjects survive to adult life The order of frequency of such displacements of organs according to Hart is stomach omentum colon small intestine liver duodenum pancreas cecum kidney (2) *Traumatic* the result of stab wounds, blows or in rare instances excessive abdominal pressure as in severe vomiting (3) *Periesophageal* or *hiatus* hernia in which a portion of the stomach passes upward through the esophageal hiatus of the diaphragm Most of these hernias are discovered in adult life and while they may be acquired or may increase in size they probably depend on congenital or abnormal weakness in the periesophageal fascia Formerly believed to be rare they are now not infrequently discovered (60 cases in 8000 examinations Ritvo) during routine fluoroscopies of the stomach For their detection fluoroscopy in the recumbent position preferably with the head slightly lower than the hips is necessary In the routine fluoroscopy of the stomach of 13 034 patients at the Presbyterian Hospital in Chicago there were found 291 diaphragmatic hernias (F H Squire) Very few of these hernias caused symptoms recognized prior to *fluoroscopy as due to diaphragmatic hernia* some were sent for fluoroscopic confirmation of the diagnosis of probable diaphragmatic hernia in the majority the hernia was an incidental finding in patients suffering from other lesions or in normal health and produced no symptoms recognized as referable to it The hernial protrusion varies in size from a small projection perhaps 1 cm in diameter to large hernias *consisting of a* considerable portion of the stomach

Symptoms —The prominent symptoms of *congenital diaphragmatic hernia* are dyspnea and cyanosis The heart is often displaced and a gurgling of gas can be heard in the chest The usual tympany in the left hypochondrium may be absent Distention by gas in the herniated stomach or colon may cause sudden increase in dyspnea or cardiac embarrassment Strangulation of the incarcerated bowel may occur In some cases extensive displacement of stomach or bowel produces slight or no symptoms and the condition is discovered only in routine physical or roentgen examination The majority of infants with this condition die when only a few days old

The *initial symptoms of traumatic hernia of the diaphragm* are those of shock severe pain in the lower part of the chest and a feeling of constriction Hiccup and often dyspnea and vomiting are present *If the* condition is due to a stab wound pleurisy or peritonitis may result The movements of the affected side are limited the heart is displaced a tympanitic note due to presence of stomach or intestine in the pleural cavity may be heard over the base of the lung and gurgling sounds due to movements of flatus heard in the chest

The symptoms of *periesophageal hernia hiatus hernia* (esophageal orifice hernia) are of importance because they *simulate those* of other diseases of the esophagus stomach biliary tract or heart Some are symptomless (14 of 60 Ritvo) The common symptoms are epigastric distress heart burn hiccup eructations of gas and food *especially* on lying down after a meal Dysphagia coming on after two or three *swallows of* food sometimes suggests malignant disease of the lower esophagus Pain over the left trapezius ridge was noted in one case Pain *on swallowing* or at night upon lying down after a full meal may be *severe* and the possibility of cholelithiasis or ulcer is suggested Persistent vomiting *sometimes of blood may occur and* severe anemia has been seen (Weitzen) Bleeding is believed to result from erosions *of the fold* of the incarcerated portion of the stomach Diagnosis depends mainly upon *the fluoroscopic* examination but as more cases *are recog*

nized and the symptomatology studied, the condition in some cases may be suspected from the symptoms Periesophageal hernia must be distinguished roentgenologically from eventration hour glass stomach esophageal or gastric diverticula relaxation of the cardia cardiospasm carcinoma of the esophagus and cardia and symptomatically from conditions such as angina ulcer of the stomach and cholelithiasis

Treatment of the extensive and of the traumatic cases is usually surgical and must be determined after a careful study of each case In many congenital cases in infants satisfactory repair is out of the question

Fig 102 —Diaphragmatic hernia Woman forty two years of age Epigastric pain with vomiting on lying down only

E M Miller (1939) has summarized the literature and added an additional case of successful operation in an infant Frank and Hamilton (1941) report the successful repair of a hernia of the diaphragm in which there was a penetrating ulcer of the herniated stomach The maintenance of the semi erect position has been advocated The danger of strangulation of herniated bowel leads to serious consideration of surgical measures in some cases in which discomfort is minimal Many periesophageal hernias especially the small ones require no treatment They are either symptomless or the symptoms are disregarded by the patient after he has been assured of the cause and more serious conditions such as cancer or ulcer have been excluded Patients with neurotic tendencies may develop aerophagia and various neuroses on the basis of the indefinite or unexplained symptoms The eating of small meals moderate exercise the avoidance of the recumbent position immediately after eating and a diet suitable for ulcer of the stomach diminish symptoms

Eventration of the Diaphragm —The term 'eventration of the diaphragm indicates a defect which is characterized by a thinning or relaxation of one leaf of the diaphragm which occupies an abnormally

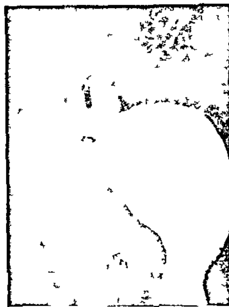

Fig 103 —Diaphragmatic hernia. Woman thirty nine years of age Mild epigastric distress only

high position It is associated in some instances with aplasia of the lung on the affected side The weight of evidence is that it is congenital in origin This condition was first described by Petit in 1790 It is of rare occurrence but during recent years a number of cases have been described

Symptoms—The symptoms of eventration of the diaphragm are indefinite Some patients complain of a rather vague gastric distress The condition is usually detected by x ray examination Funk has called attention to an increased outward movement of the costal margin on the affected side in inspiration which is due to the fact that the intercostal muscles on that side have little

opposition from the weakened diaphragm This observation has been confirmed by Korns

Treatment—Surgical treatment may be of value in certain cases

ANOMALIES OF URINARY SECRETION

Anuria.—Anuria is total suppression of urine by the kidneys. A satisfactory working classification of the various etiologic causes of anuria divides them into three groups: (1) prerenal, (2) renal, and (3) postrenal. Prerenal anuria is seen in states of shock with low blood pressure where the pulse pressure falls to such a low level that urinary secretion ceases. Anuria of renal origin may occur in (1) the extreme congestion of acute nephritis, (2) from cortical infarction, usually bilateral and occurring postoperatively, (3) following transfusion with incompatible blood which blocks the tubular systems with precipitated hemoglobin, (4) blockage of the tubular system with crystals of the sulfonamide drugs, and (5) in extreme cases of degenerative nephritis caused by such heavy metals as lead, mercury, and phosphorus. A calculus in the pelvis of the kidney may also cause anuria, either unilateral or bilateral, depending upon its location. Postrenal anuria includes those conditions where (1) the ureter is blocked by a stone or new growth, and (2) blockage of the ureter, either unilateral or bilateral, by crystals of the sulfonamide drugs precipitated from the urine. Anuria may follow severe crushing injuries, and rarely the mere passing of a catheter has been known to bring on anuria through reflex nervous action.

In anuria the hydronephrosis which so frequently accompanies partial obstruction of the urinary tract does not tend to develop, and there may be remarkably few *symptoms*. Headache, vomiting, and lumbar pain are the most common. Although nonprotein nitrogen, urea, uric acid, and creatinine are retained in the blood, frequently in even larger amounts than during the terminal stages of uremia, convulsions occur rarely and consciousness is retained almost until death. The reason for this absence of convulsions and constitutional symptoms so characteristic of uremia is not known, but it must be remembered that the mere retention in the blood of any of the recognized nonprotein nitrogen bodies is not in itself sufficient cause for uremia.

Anuria must be clearly differentiated from the condition in which urine is secreted by the kidneys and retained within the bladder. This distinction can be made by either physical examination or by catheterization. Stricture of the urethra, prostatic obstruction, or a spinal cord lesion interfering with the nervous control of the bladder may cause retention of urine. Bladder tumors are suprapubic and median in location.

The severity of anuria varies directly with the duration, which may be several hours or many days. Adams has reported recovery after total suppression of urine for nineteen days.

Treatment.—Treatment of the anuria associated with shock is dependent upon the shock therapy, which is designed to restore the plasma protein and blood volume, elevation of the blood pressure and restoration of the pulse pressure. In the treatment of anuria associated with acute nephritis, hot applications, free purgation, and high hot colonic irrigations have proved valuable. Intravenous administrations of glucose (300 cc. of a 20 per cent solution twice a day) are also beneficial. Intravenous administration of hypertonic (150 cc. of 10 per cent) sodium chloride solution has been reported to be effective. Similar therapeutic measures are advisable when anuria is due to the extreme degeneration caused by chemical poisons. Anuria following transfusion with incompatible blood may be severe and protracted. Recovery occurs in about 80 per cent of the cases with no residual damage of the kidneys. Complete blockage of a ureter with crystals of the sulfonamide drugs demands intravenous administration of large quantities of saline and may require surgical drainage of the pelvis of the kidney and lavage of the ureter. In cases caused by stone in the ureter or by obstruction of the ureter through new growths surgical treatment is imperative.

Hematuria—Hematuria is the discharge of blood in the urine In a small percentage of cases the source of the hemorrhage can not be located but in the majority, various available signs permit determination of the correct etiology

Essential hematuria is the term applied to hematuria of unknown origin and comprises 2 per cent of the total cases In this bleeding is usually spontaneous painless intermittent and not so severe as to lead to exsanguination Certain cases included in this group have been caused by varicosity of the veins of the kidney pelvis or papillae Ureteral catheterization has demonstrated that the hemorrhage of essential hematuria is usually unilateral X ray examination is always negative This condition is usually found in individuals less than thirty years of age

Hematuria of Known Etiology—In by far the larger number of cases hemorrhage can be located and ascribed to a definite cause

1 Renal Disturbances—Acute nephritis pyelonephritis and the acute exacerbations of chronic nephritis especially when the kidneys are secondarily contracted may be accompanied by hematuria of all degrees of severity Passive congestion of the kidneys during marked cardiac failure is a common cause for the presence of a few red blood cells in the urine New growths especially hypernephromata cause profuse bleeding In both early and advanced tuberculosis red cells as well as pus corpuscles appear in the urine but without pyogenic organisms unless there has been secondary infection Other causes of renal hematuria are certain chemical agents such as urotropin turpentine cantharides and carbolic acid the renal infarction secondary to endocarditis and such systemic diseases as purpura, leukemia and malaria The sulfonamide drugs may cause hematuria and rarely it has followed from the use of heparin to prevent the formation of a thrombus Stone in the kidney is the commonest cause of renal hematuria

2 Pathologic Conditions of the Urinary Tract and Bladder—Among the most frequent causes of hematuria are stone in the ureter or bladder tumors of the bladder or prostate tuberculosis ulceration and rupture of the veins of the bladder Occasionally gonorrhea may cause bleeding from the urethra

3 Mechanical Disturbances—Traumatic rupture of the kidney bladder, or posterior urethra as well as injury of the urethral mucosa by catheterization, may also produce hematuria

4 Other Causes—Strenuous exhausting physical exercise and exposure to cold are frequently followed by the temporary appearance of a few red blood cells in the urine without evidence of renal disorder Hematuria has occurred after the use of tetanus antitoxin an allergic manifestation When the blood prothrombin is low due to a deficiency of vitamin K mild degrees of hematuria are seen

Diagnosis—In all types of hematuria red blood cells frequently crenated and albumin are present in the urine As blood cells disintegrate rapidly in alkaline urine the specimens should be examined promptly after collection

The exact character of the *urine* depends on the source of blood There are several means by which this may be ascertained If blood appears at the beginning of micturition it comes from the anterior urethra, if at the end from the vault of the bladder as a rule and if throughout micturition it is mixed with the urine hemorrhage is from the kidney In the latter case blood clots and blood casts may be present and the color of the urine varies from a smoky tinge to bright red Not infrequently children and young adults void bright red urine which is referable to the pigment of beets

Frequently however special examination is necessary before the point of bleeding can be exactly located Cystoscopy ureteral catheterization and intravenous excretory urograms are of great value

Hemorrhoids as well as vaginal discharges may be confusing factors A diagnosis of *essential hematuria* can be made by a process of elimination and should be accepted with reluctance In essential hematuria be suspicious of an early malignancy

Treatment—Rest in bed supplemented by full doses of morphine if necessary is indicated in hematuria of whatever type Cold applications to the lumbar region are often helpful In certain cases of essential hemat

uria recovery has followed simple distention of the pelvis of the kidney with fluid while in others intrapelvic lavage with silver nitrate and adrenalin has proved of only temporary benefit Moccasin venom which seems to exert some action on the capillaries has been successfully used in essential hematuria Also the intravenous injection of the sodium salt of cevitamic acid has stopped the hematuria in obscure cases which would argue that there is a lack of an intercellular cement substance which the vitamin C supplies When hematuria is related to deficient blood prothrombin vitamin K administration will correct it Vitamin P the capillary permeability vitamin when used in conjunction with vitamin C has been successful in controlling hematuria in several diseases Nephrectomy should be performed only as an emergency measure in the most severe cases of unilateral bleeding

Hemoglobinuria —Hemoglobinuria occurs when the blood destroying organs are unable to handle all the damaged red blood cells in circulation and hemolysis consequently takes place in the blood stream Normally the endothelial cells of the spleen bone marrow and hemolymph glands take up these damaged corpuscles and convert their iron containing pigment in part into bilirubin which is carried by the circulation to the liver for excretion Under these conditions the iron forming fraction of the molecule is separated by hepatic action and retained for further use in the body while the remaining portion is converted into bile pigment and excreted Hemoglobin has a renal threshold in man but in terms of its plasma concentration this threshold is very variable It is most constant in terms of hemoglobin per kilogram of body weight 92 mg per kilogram for men and 72 mg per kilogram for women The threshold mechanism operates in the kidney similar to that of glucose excretion namely mechanical filtration through the glomeruli followed by reabsorption by the tubular epithelium Only when the concentration in the glomerular fluid exceeds the absorptive capacity does hemoglobin pass into the urine

Hemoglobinuria falls into two groups (1) toxic and (2) paroxysmal

Etiology —The etiology of the toxic form is variable Chemical poisons such as carbolic acid potassium chlorate pyrogallic acid carbon monoxide muscarine and cobra venom may produce rapid hemolysis while the toxins generated by the exciting agents of certain infectious diseases not infrequently have a similar result Those of scarlet fever yellow fever, typhoid syphilis and certain types of hemolytic jaundice should be cited In malaria hemolysis is caused by the plasmodium which actually enters the red corpuscle multiplies and finally causes rupture Sometimes hemolysis follows the introduction of foreign protein into the blood stream as for instance in transfusion and serum therapy or after extensive burns when the tissue proteins are partially split Rarely hemoglobinuria may be due to a lesion of the kidneys such as infarction and usually occurs only on the side involved Finally exposure to cold and violent exercise are said to increase the fragility of the red cells so markedly that their hemoglobin is liberated and hemoglobinuria ensues This has been noted in young soldiers following strenuous exertion It is interesting that in two conditions namely acute nephritis and infarction of the kidney hemoglobinuria may occur without hemoglobinemia

When hemoglobin is present the color of the urine varies from red to dark brown If specimens are allowed to stand a heavy brownish sediment precipitates Microscopic examination of the sediment reveals no formed red cells but the spectroscope demonstrates the characteristic bands of hemoglobin Causes other than hemoglobinuria that may cause pink red or black urine are hematuria porphyria (urofuscin) myoglobinuria pigment of beets phenolphthalein and neoprontosil

Treatment —The form of treatment depends upon the etiology

Albuminuria —The term albuminuria as employed clinically means proteinuria and is evidence of increased permeability of the glomerulus and Bowman s capsule to large protein molecules Etiologically there are two types physiologic and pathologic

Physiologic Albuminuria —ORTHOSTATIC ALBUMINURIA —For the type of albuminuria in which serum protein mostly albumin appears in the urine only after standing or sitting and disappears after reclining the term orthostatic albuminuria is employed

This type which is most commonly seen in young patients seems to occur usually in thin individuals with poor muscular tone and marked evidence of vasomotor instability

There are two main theories as to its *etiology* (1) that of Erlanger and Hooker which ascribes the albuminuria to diminished pulse pressure and (2) that of Jehle which is based on the belief that the increased lordosis frequently present interferes *with the renal circulation Later studies by* Rytaud following diodrast injections have shown anatomic renal defects which may be a causative factor

Careful studies of renal function have also shown some impairment although of a transitory nature which occurs synchronously with the albuminuria

The quantity of albumin in the urine varies from a faint trace to as much as 8 to 10 Gm per liter Casts are rarely present

It is interesting to note that during orthostatic albuminuria when the body is horizontal a low pulse pressure artificially produced by mechanical lordosis causes albumin to appear in the urine

In many patients the condition is outgrown or disappears as the general state of health improves in others correction of lordosis with a spinal brace is beneficial The prognosis is good

Pathologic Albuminuria —1 Secondary to Nutritional Changes —Normally the kidneys do not permit transmission of serum albumin through the glomerular epithelium into the tubules but circulatory changes may so alter the permeability of the membrane that the protein can pass As soon as renal circulation *is reestablished* however excretion of albumin stops Albuminuria of this type occurs during passive congestion of the kidney severe anemia and after strenuous muscular work and cold bathing The quantity of albumin eliminated in the urine is usually small If casts are present they *are of the hyaline or granular type*

2 Secondary to Toxic Action —Slight albuminuria accompanies the pyrexia of all the acute infections The cloudy swelling of the tubules which is caused by the toxemia rapidly disappears during convalescence In this type the urine may contain a *few* casts

Chemical poisons also produce varying grades of albuminuria by their action upon the kidney Mercury lead ether and chloroform are the more common of these *Exposure to intense sunlight* is frequently followed by a transitory albuminuria

3 Associated with Definite Lesions of the Genito urinary Tract —(*a*) In such organic diseases of the kidney as acute subacute or chronic nephritis the degree of albuminuria varies greatly and is dependent upon the nature and severity of the injury of the glomerular capillaries During advanced chronic interstitial nephritis with primarily contracted kidneys only the faintest trace of albumin may be excreted while during nephritis of the chronic parenchymatous types when the contraction is secondary very large amounts are present in the urine Albuminuria occurs as well in suppurative nephritis amyloid or fatty degeneration of the kidney and as the result of many new growths in the kidney

(*b*) It also follows infection of the renal pelvis ureter bladder prostate and urethra With pus or blood in the urine there *is al*ways a small amount of albumin but usually there are no casts

Prognosis —Within recent years our interpretation of a small quantity of albumin in the urine has undergone a change In young patients albuminuria cannot be considered pathologic until the possibility *of cyclic or* orthostatic albuminuria has been excluded A trace of albumin in the urine after the fortieth year may be merely an evidence of the retrogressive changes of age and frequently goes hand in hand with the slight rise in blood pressure which is physiologic *If associated with increased* arterial tension or the presence of casts or red blood cells in the urine albuminuria is of significance but cannot be truly evaluated without careful consideration of the past *history and* physical condition of the patient

Albumosuria —When proteoses enter the blood stream the tissues seem to be unable to use them and they appear in the urine This is known as albumosuria or proteosuria It is a condition associated with the rapid breaking *down of tissue* such as occurs in suppuration of all kinds intestinal obstruction severe burns resolution of pneumonia involution of the uterus acute yellow at

rophy and leukemia In chronic degenerative parenchymatous forms of nephritis both albumin and globulin are excreted in considerable quantities

Myelopathic Albumosuria —This term is used to denote the presence in the urine of a protein first described in 1818 by Bence-Jones as a new substance This is not a true albumose but is allied to the more simple proteins It seems to be definitely related to diseases of the bone and appears in the urine of about 80 per cent of the cases of myeloma In leukemia, chloroma myxedema (one case reported by Fitz) and nephritis it has also been found in the urine

The quantity recovered in the urine bears no relation to diet The output is constant throughout the twenty four hours and in some cases of myeloma amounts to 30 to 70 Gm daily Just how the kidney can excrete such quantities without organic change or simultaneous filtration of serum albumin is difficult to explain

The exact source of this Bence-Jones protein is not known but the fact that the body cells react to its presence by the formation of a 'precipitin proves it to be synthetic It coagulates at temperatures between 49 and 60 C does not dialyze is precipitated from urine containing 25 per cent nitric acid in such a form that it disappears on boiling but reappears on cooling and gives up sulfur in the presence of alkalis

Treatment depends upon the etiologic basis of the condition Multiple myelomata run a fatal course Benzol has been advocated as a therapeutic measure for this type of albumosuria in leukemia

Bacteriuria.—It is well known that a few bacteria frequently filter through the kidney epithelium and are passed in the urine without causing any symptoms or cellular reaction When large numbers appear in the urine the condition is termed bacteriuria or bacilluria This is of two types—primary and secondary The primary which is the more common is associated with cellular reaction and is caused by a focus of infection in the genito urinary tract The urine is characteristically cloudy when voided and contains pus cells When the cause of the condition is tuberculous pyogenic organisms are usually absent More recent studies have indicated that in primary bacilluria there is usually a local lesion in the cortical area of the kidney Secondary bacilluria is not uncommon in the acute infections in which there is a general systemic distribution of the organisms as frequently found in staphylococcic and streptococcic septicemias It accompanies typhoid fever, pneumonia in many cases and the early stages of meningococcic meningitis Recent observations tend to indicate that in many secondary bacillurias there are local lesions in the cortex of the kidneys

Treatment —In the treatment of primary bacteriuria the sulfonamide drugs hold first place For the coccal infections one should use sulfathiazole in doses of 2 to 4 Gm (30 to 60 grains) per day Sulfanilamide in similar dosage is most effective in colon bacillus infections

Pyuria —Pyuria is the presence of pus in the urine It is a condition associated with infection of any part of the genito urinary tract from Bowman s capsule in the kidney to the external meatus of the urethra

The *causes* fall naturally into three groups (1) pyelitis pyelonephritis and pyonephrosis (2) cystitis (3) urethritis of gonorrheal or other origin and tuberculosis or rupture of abscesses of the genito urinary tract

The presence of significant quantities of pus in the urine is evidenced quite definitely by cloudiness at the time of voiding by the precipitation on standing of a stringy grayish precipitate which can be differentiated from the phosphates with heat and acid and from the urates by heat alone and by the presence of albumin Microscopic examination is of course the surest test Normal urine contains only a few well preserved leukocytes

In determining the exact cause of pyuria several facts must be kept in mind During pyelitis and the pelvic inflammation produced by a calculus pyuria is usually constant That resulting from tuberculosis of the genito urinary tract is also persistent During pyonephrosis and the conditions associated with large abscesses of the kidney on the other hand pus may be discharged intermittently into the urine The chemical reaction of the urine in pyuria caused by cystitis varies according to the type of infecting organism and in tuberculosis of the

genito urinary tract is acid Pyuria of tuberculous origin is not accompanied by bacteriuria Large quantities of pus may be present after rupture of an abscess into the genito urinary tract Certain confusing factors must always be considered before diagnosis is made definite Differentiation between cystitis and chronic prostatitis or abscess of the prostate is necessary In the female the absence of leukorrhea should be ascertained by inspection and catheterization In all chronic cases of pyuria which are resistant to treatment one should be careful to rule out tuberculosis

Treatment—The sulfonamide drugs are most useful in treatment Make a smear from the urinary sediment and stain by Gram s method Then use the appropriate drug according to the type of organism present sulfathiazole for coccal infections and sulfanilamide for gram negative bacillus infections No known drugs are effective with B proteus infections

Chyluria, Nonparasitic—Chyluria and lipuria of nonparasitic origin are essentially the same In both there is fat in the urine The only point of difference is that in chyluria none of the fat is visible as minute droplets while in lipuria most of the fat is in a fine suspension

Fat is present in the urine more commonly than was formerly supposed Although small amounts are frequently found in the urine of patients with *diabetes mellitus* when it is accompanied by lipemia and in nephritis especially of the parenchymatous type as much as 6 per cent has been reported present in some cases It is thought that this fat passes directly from the blood through the kidney epithelium into the urine In certain types of nephritis extensive fatty degeneration of the kidney cells results in the appearance of a large quantity of non visible fat in the urine

Mechanical blocking of the lymphatic system is as a rule the cause of the more marked cases of chyluria in which the urine is opaque and whitish like milk Generally by rupturing the deeper lymphatics a leak is produced in the kidneys or bladder wall through which fat enters the urine Osler has reported a case in which obstruction of the thoracic duct was followed by rupture of the lymphatic vessels leading to the bladder Such chyluria is more marked after meals increases on reclining and is frequently associated with hematuria The simultaneous elimination of blood and fat in the urine is known as *hematochyluria*

In the *diagnosis* of nonparasitic chyluria great care must be used to exclude *Filaria bancrofti* from the possible etiologic agents

Creatinuria—The presence of creatine in the urine has not as yet been fully explained During early childhood it is normal for both sexes In the normal male creatinuria ceases permanently at about seven years of age in the female on the other hand it persists until puberty and recurs with each menstrual period during pregnancy and during *postpartum* involution of the uterus

Although many of the phenomena involved in the transformation of creatine into creatinine are known the exact metabolism and source of these substances is an unsolved problem Creatine is present in the body in large quantities the voluntary muscles contain the highest concentration the brain and testes are next in order and in the circulating blood the concentration is lowest Muscular exercise seems to have no effect upon the rate of excretion of creatine but variations in the ability of the muscles to utilize carbohydrate have a marked influence Creatine appears in the urine for instance during the muscular dystrophies and atrophies accompanied by diminished carbohydrate metabolism In such conditions as fasting or *diabetes mellitus* when the carbohydrate and glycogen depots are depleted creatinuria also occurs as well as in cancer of the liver hyperthyroidism cyclic vomiting fever certain pituitary disturbances and phosphorus and hydrazine poisoning Creatinuria has been found in eunuchs adult males with sexual underdevelopment and in most adult male and female schizophrenics It is interesting that methyl testosterone increases creatinuria while intramuscular injection of testosterone propionate decreases its excretion When occurring in hyperthyroidism it can be suppressed by large doses of vitamin C Hypoglycemia and creatinuria seem to be closely related Although the significance of creatinuria is not known careful studies have demonstrated that it is not an index of cellular destruction

Lithuria—The presence of excessive amounts of uric acid or urates in the urine is called lithuria

In man and the higher apes uric acid is the end product of the breakdown of the nucleic acid which is contained in certain protein molecules Uric acid circulates in the blood stream as a monosodium salt, for the most part in colloidal or protein combination (Benedict) It is excreted easily by the kidney in the form of sodium potassium and ammonium salts These urates form a pinkish precipitate upon standing which is soluble in urine when heated and appears under the microscope as amorphous granules Frequently however acid phosphates are present in the urine in such high concentration that the basic radical is withdrawn from these salts and uric acid precipitates in the characteristic crystals known as "cayenne pepper grains These may be colorless but are usually a rich mahogany brown because of the pigments in the urine The factors which favor precipitation of uric acid are (1) acidity (2) concentration (3) the presence of large amounts of neutral phosphate and (4) increased excretion of uric acid Both increased ingestion of foods rich in nuclein and increased catabolism of the nucleoproteins of the tissues augment excretion of uric acid

The output of uric acid decreases immediately before an attack of gout and increases greatly on the second or third day after onset

Uric acid crystals and urates frequently take part in the formation of calculi which are not opaque to x ray Uric acid crystals may cause renal colic It is interesting that excessive uric acid excretion may be unilateral

Because of a better understanding of the solubility of uric acid lithuria is considered of much less importance than formerly Prolonged alkalinization of the urine may dissolve uric acid stones

Treatment—Administration of a diet free from purine bodies which are found in meat fish liver sweetbreads brains etc removes the source of exogenous uric acid Excretion of uric acid is increased by the salicylates colchicum and especially by atophan The prolonged administration of atophan however may have a toxic effect upon the liver Ingestion of alkalis reduces the acidity of the urine and an abundant fluid intake lowers its concentration

Fig 104—Calculus of bladder The central core and outer layers are made up of calcium oxalate with ammonium magnesium phosphate filling in the middle layer (From the collection of the Department of Genito-Urinary Surgery Royal Victoria Hospital)

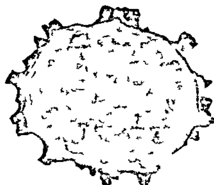

Fig 105—Cross section of the same calculus as in Fig 104

Oxaluria—Oxaluria is the presence of undue quantities of oxalic acid and oxalates in the urine

In 1838 Donne first described the calcium

oxalate crystals contained in *most acid* urine Subsequently, investigation has shown that the normal urinary output of oxalic acid (in the form of calcium salt) is between 30 to 40 mg per day The blood level averages 3 to 4 mg per cent A majority of this is derived from food but that part of it is a normal product of metabolism has been proved by the fact that during prolonged fasting the excretion of oxalic acid continues Since the *solubility* of calcium oxalate in urine is independent of the degree of acidity and depends on colloidal conditions and since urine is normally supersaturated with calcium oxalate crystals of this salt may be seen in acid, neutral and alkaline specimens

Absorption of the insoluble calcium salt which is present in most vegetables is facilitated by the hydrochloric acid of gastric juice and by excessive fermentation of carbohydrates in the intestine Calcium inhibits absorption of the salt

In certain individuals with so called oxalic acid diathesis calcium oxalate stones tend to form They usually develop first in the pelvis of the kidney and are so hard and rough as to cause frequent bleeding Crystals alone may cause hematuria frequency and lumbar pain Calcium oxalate stones have a marked density and cast an opaque shadow by x ray They may form in the bladder behind prostatic or urethral obstruction

Treatment —The purpose of treatment is to facilitate solution of oxalates in the urine by increasing its acidity with double acid phosphates raising the magnesium content and lowering the calcium content Consequently the diet should be rich in protein contain little carbohydrate and oxalic acid Rhubarb *spinach potatoes strawberries* beets tomatoes tea coffee and cocoa must therefore be avoided Acid sodium phosphate increases the acidity of the urine satisfactorily

Cystinuria —A rare disturbance of the intermediary metabolism of protein results in cystinuria—the passage *of cystine in the* urine—or in the formation anywhere in the genito urinary tract of calculi composed of *pure cystine crystals* Under normal conditions cystine which is an amino acid containing sulfur is broken down into simpler compounds but during some metabolic con*ditions it is directly* excreted More recently it has been shown that the urinary cystine comes from the protein sulfur which is present in the *protein molecule as methionine* Difficult to understand is the fact that the level of cystine excretion by a cystinuric is not increased by ingestion of cystine itself but is increased by proteins rich in sulfur

The *occurrence* of cystinuria in three generations of one family is evidence of the possibility that it is caused by some hereditary condition

Cystine was first discovered by Wollaston *in 1910 in a urinary calculus The typical* hexagonal crystals which form in the urine are soluble in concentrated mineral acids and alkalis Cystine stones are often multiple and cast a uniform shadow with x rays Unless these stones are formed, cystinuria is accompanied by no symptoms The tyrosine and leucine crystals which appear in the urine of some patients are evidence of a still more far reaching abnormality of met*abolism*

Treatment —This metabolic abnormality is a lifelong and incurable condition An alkaline ash type of diet with low protein content is indicated During cystinuria the fluid intake should be abundant, and the protein content of the diet low If a calculus has formed administration of *alkali* (6–10 Gm of sodium bicarbonate per day) is advisable and intrapelvic lavage with an alkaline solution may be helpful Such treatment is followed by disappearance of cystine crystals from the urine and complete dissolution of the stone has been reported

Phosphaturia —Normally the kidneys excrete between 1 and *5* Gm of *phosphoric* acid (P_2O_5) in the form of phosphates but *at times either* this elimination becomes excessive or the phosphates are precipitated by a change in the reaction of the urine Such abnormal excretion and precipitation is called phosphaturia *The phosphates* thus excreted are of two types the alkaline (Na K) and the earthy (Ca Mg) The most *abundant are the* sodium compounds which play an important part in the regulation of the acid base equilibrium of the body Calcium phosphate is the most important of the earthy salts

Undue precipitation of phosphates occurs when infection of the genito urinary tract

is accompanied by the excretion of alkaline urine It frequently results in the formation of stones in the bladder renal pelvis and urethra These are usually composed of crystals of ammonium magnesium phosphate calcium phosphate calcium oxalate and ammonium urate The magnesium salt is the most abundant Calcium phosphate stones are the common ones found with prostatic obstruction

During phosphaturia the urine is alkaline and cloudy when voided but clears on the addition of acid The earthy (Ca Mg) phosphates present are converted by heat into monocalcium and tricalcium phosphates These produce a fine turbidity which disappears when acid is added Phosphaturia can be unilateral and can cause attacks of renal colic

Treatment should remove any infection present and lower the intake of calcium which renders the phosphates more soluble Acid sodium phosphate should be administered in order to make the urine acid A free fluid intake is advisable Continuous irrigation for six hours per day has resulted in solution of bladder and renal pelvis calculi of this type A nonirritating citric acid solution buffered to approximately P_4 has been used

Indicanuria —The term indicanuria is applied to the appearance of indican in the urine in comparatively large quantities only for as much as 12 mg per day is excreted by the normal individual

Urinary indican is derived from the indole generated by bacterial putrefaction in the intestines The action of the colon bacillus upon tryptophan an amino acid which is present in the intestine is of special importance in this process The indole is absorbed by the blood oxidized and joined with potassium sulfate in the liver to form indoxyl and finally indican

Indicanuria is the best index of intestinal putrefaction and is most marked during obstruction of the small intestine It occurs whenever pus collects in the body as well as during peritonitis and some wasting diseases Excretion of small amounts of indican is normal in the newborn

Because of the slight toxicity of indole and indican constitutional *symptoms* do not develop until considerable quantities have been absorbed Large amounts may be related to definite clinical symptoms affecting mainly the nervous system and taking the

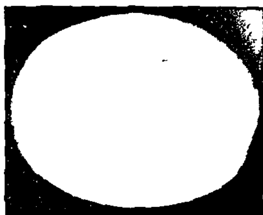

Fig 106 —Calculus of bladder composed mainly of ammonium magnesium phosphate crystals (From the collection of the Department of Genito-Urinary Surgery Royal Victoria Hospital)

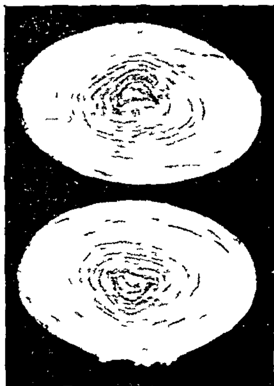

Fig 107 —Cross section of the same calculus as in Fig 106 Note concentric structure

pattern of convulsive seizures of an epileptiform type

Indicanuria is demonstrated by a simple test which consists of the addition of a strong oxidizing agent and subsequent shak

ing with chloroform The indigo which forms from indican (potassium indoxyl sulfate) in the presence of the oxidizing agent gives its characteristic blue color to the solution containing chloroform

Treatment should consist of limiting the meat and increasing the milk intake Lactose inhibits the growth of putrefaction organisms Acidophilus milk has been helpful In the case of achlorhydria hydrochloric acid by mouth will favor a more complete digestion of meat

Melanuria —In certain pathologic conditions the production of excess melanin, the normal coloring matter of the skin hair and choroid of the eye, results in the appearance of this pigment in the blood and urine *i e* in melanemia and melanuria This occurs during the course of Addison s disease and also in rare cases in which local degeneration of the tissues of melanotic tumors liberates large quantities of melanin In the latter case as much as 500 Gm may be present in the body Melanin is normally very abundant in the skin of the black races and it has been estimated that the skin of a single individual may contain 1 Gm

Probably the *source* of the several closely related bodies now classified as melanin is to be found in certain chromogen groups of the protein molecule and not in hemoglobin

Although urine which contains melanin may be darkly colored when voided its appearance is usually normal This is explained by the fact that the melanin circulating in the blood is reduced by the liver to colorless *melanogen*—a substance which turns black when exposed to air or to other oxidizing agents Urine may be colored dark brown by only 0 1 per cent of melanin

According to Helman the presence of true melanogen in the urine can be determined by three reactions the precipitation of a black substance on the addition of ferric chloride the solution of this substance in the presence of sodium carbonate to form a black solution and the formation of a black or brownish powder when mineral acid is added to the black carbonate solution All of these tests must be positive before melanogen can be said to be present

Alkaptonuria —Alkaptonuria or the presence of alkaptone (homogentisic acid) in the urine is rare generally persists throughout life, and is more common in the male than in the female It is the result of a harmless anomaly of the intermediary protein metabolism which appears to bear some relation to the recessive characters of mendelian inheritance First cousin marriages have frequently produced alkaptonuric offspring

Although the *clinical manifestations* of alkaptonuria were well described by Marcet in 1823 the presence of alkaptone or homogentisic acid in the urine was not recognized until 1887 At this time Marshall isolated the substance in the urine but called it glycosuric acid Its principal precursors are the tyrosine and phenylalanine of the protein molecule Relatively as much is produced by endogenous protein as by that contained in the food although of course the actual quantities derived from the two sources are of very different magnitude Normally alkaptone is broken down by the tissues of the body—probably by the liver alone—before excretion but in certain individuals it may be isolated in the circulating blood and is eliminated in the urine as an ammonium salt Experimental work on white rats has indicated that homogentisic acid is an intermediate product of the normal metabolism of phenylalanine It is interesting to note that light is given off during the oxidation of homogentisic acid in alkaptonuric urines This light is visible as a faint glow in the foam after shaking This fact may explain certain luminous urines reported in the early literature

Urine which contains alkaptone stains the linen tends to turn dark when exposed to the air and is frequently dark when voided If mixed with an alkali it becomes black The addition of dilute ferric chloride solution drop by drop produces a transitory blue coloration Such urine reduces Fehling s solution atypically does not ferment and is optically inactive

In rare cases of alkaptonuria the cartilages turn dark (ochronosis) and there is a tendency to the development of chronic arthritis Since nonspecific fixation of the blood is often associated with the excretion of homogentisic acid great care must be used in interpreting the Wassermann reaction when patients are known to be alkaptonuric

Treatment—As a rule there are no subjective symptoms which require treatment Fluids should be taken freely, and if desirable the quantity of alkaptone in the urine may be reduced by decreasing the protein content of the diet Klein and Block have reported that intramuscular injections of liver extract freed the urine of homogentisic acid for eight to ten hours after a four to six hour interval

Pneumaturia.—Pneumaturia is the passage of gas with the urine It is known to occur after irrigation of the bladder and following cystoscopic examination of patients in the knee-elbow position as well as during chronic cystitis When the gas is derived from an extraneous source its appearance in the urine is only temporary for elimination is hastened by rapid absorption into the blood Intravesical generation of gas is most common during chronic cystitis and is caused by gas forming organisms—the colon bacillus the yeast fungus or the *Bacillus aerogenes capsulatus* In such cases the urine is foamy when voided and usually contains sugar Rarely vesico intestinal fistulae secondary to carcinoma of the sigmoid ruptured diverticulum of the descending colon or sigmoid or *diverticulitis* are associated with a cystitis of this type

The *symptoms* are usually those of mild cystitis The urine may be foamy when voided or the gas may be passed at the end of micturition

Pneumaturia may be demonstrated by the passage of urine under water or by submerging the end of the catheter

PAROXYSMAL HEMOGLOBINURIA

Definition.—Paroxysmal hemoglobinuria is a rare disease characterized by transitory hemoglobinuria following exposure to cold or occasionally after exertion and by the presence in the blood of an autohemolysin which unites with the red blood cells only at low temperature The disease is a manifestation of late syphilis either congenital or acquired

History—In 18?4 Dressler wrote about "intermittent albuminuria and chromaturia," and set forth the first good description of paroxysmal hemoglobinuria. During the last half of the nineteenth century numerous reports appeared The clinical features were well defined and the disease soon became generally recognized as an entity Donath and Landsteiner (1904) made an important contribution when they observed that the blood of these patients contains an autohemolysin which may be demonstrated by a simple *in vitro* test.

Etiology—Syphilis is now accepted as the essential cause of the disease The paroxysmal hemoglobinuria may or may not show other signs of late syphilis but the Wassermann reaction is almost invariably positive Nearly all of the reported cases have occurred either in children with congenital lues or adults long past the secondary stage of acquired syphilis The characteristic autohemolysin may be found in certain other syphilitics especially in patients with general paresis who have not had hemoglobinuria

Pathology—Although paroxysmal hemoglobinuria is intimately related to late syphilis it is possible by appropriate methods to remove from the blood the *autohemolysin* without weakening the Wassermann reaction The titer of the autohemolysin in the serum may show variation from day to day it may persist after the patient has ceased to have paroxysms upon exposure to cold In the serum from different patients it shows varying degrees of thermolability The writer has studied one patient whose

autohemolysin was destroyed at 47.5° C for thirty minutes so that fresh complement failed to reactivate it A specimen from another patient was not destroyed at 55° C for thirty minutes The blood of the paroxysmal hemoglobinuric contains an isohemolysin probably identical with the autohemolysin, at least efforts at separation have been unsuccessful

The *Donath and Landsteiner phenomenon* reveals one of the fundamental features of the mechanism which operates during a paroxysm The test tube reaction in its simplest form is carried out by chilling the patient s blood to about 5° C for ten minutes and then warming it to 37° C, when hemolysis occurs Normal blood so treated shows no hemolysis Since the reaction requires complement which in human blood is usually not abundant more constant results are obtained if one separates the serum makes a suspension (5 or 10 per cent) of the red blood cells and adds fresh guinea pig complement In the test tube reaction more hemolysis occurs if a heavy suspension of red blood cells is used and if the chilling is of short duration—seven to ten minutes rather than thirty to sixty minutes Slight union of the autohemolysin with the corpuscles may occur at a temperature as high as 16° C With lower temperatures the union is more complete

In the spontaneous paroxysm it seems quite probable that blood in superficial capillaries might be chilled to 15° or 16° C Union of the autohemolysin and red blood cells would then occur In the presence of complement hemolysis results after the chilled blood has passed from the surface of the body to the higher temperature of internal blood vessels Hemoglobinuria follows It has been shown however that attacks can be artificially produced by exposing the surface of the patient s body to a temperature (18° C) higher than the highest temperature at which union of the hemolysin and the red blood cells can be demonstrated *in vitro* The urinary findings occur whenever the free hemoglobin in the blood rises above the renal threshold of hemoglobin excretion In case the hemolysis is so slight that the renal threshold is not exceeded an abortive paroxysm occurs—hemoglobinemia with mild symptoms and no hemoglobinuria the so called "*petit mal* of hemoglobinuria The appearance of urobilin in the blood results from the increase of free hemoglobin the precursor of bile pigments which in turn constitute the mother substances of urobilin Extrahepatic formation of bile pigment or excessive production in the liver explains the slight jaundice not infrequently seen following the paroxysm Recently Harris Lewis and Vaughan have demonstrated a dermolysin in the plasma of one of these patients The dermolysin united with the cells of the skin only at low temperatures subsequent warming of the skin caused edema and urticaria The skin of syphilitic patients without paroxysmal hemoglobinuria could be passively sensitized to cold by intracutaneous injections of dermolysin containing serum

Symptoms—Between the chilling which may be surprisingly slight and the onset of the paroxysm there is a *latent period* varying from a few minutes to six or eight hours During this time the leukocyte count may drop to 2000 or 3000 with a relative increase in lymphocytes With the onset of the attack the number of lymphocytes decreases and a slight polymorphonuclear leukocytosis occurs The attack consists of malaise often headache pain in back and legs or abdomen chilly sensations or a shaking chill, transitory fever during which the temperature may be 104° F or higher and cyanosis Some patients show a temporary rise in systolic and diastolic blood pressures of 50 to 100 mm of mercury Frequently the liver and spleen enlarge during an attack In a few cases the phenomena of Raynaud s disease are associated with the attacks or other manifestations of vasomotor disturbance such as urticaria or vesicular lesions The urine is dark red or Burgundy color often described as black by the patient It contains hemoglobin methemoglobin hematin and hyaline granular and pigment casts and urobilin The presence of the pigment uro erythrin has also been demonstrated In these cases the urine is rose colored In freshly passed specimens intact erythrocytes may be found The hemoglobin may be present in only one specimen of urine or it may persist for a day or two Following the attack *mild jaundice* is common In the interval between attacks the

patient may be in good health but not infrequently there are symptoms due to other manifestations of late syphilis When attacks have been repeated at short intervals *secondary anemia* is commonly present

Diagnosis —The history of transitory excretion of dark colored urine during the winter months following exposure to cold or exertion a positive Wassermann reaction and stigmata of late syphilis the Donath and Landsteiner reaction in the drawn blood and the artificial production of an attack by immersion of hands or feet in ice water provide the data which establish diagnosis Without a positive Wassermann reaction the diagnosis is uncertain because there are other types of transitory hemoglobinuria unassociated with syphilis for instance the *Marschhamoglobinurie* (Fleischer, Schellong) in which the paroxysm is induced by a long march or walk The writer has observed one case of this type in a college student A brisk walk of several miles sufficed to bring on a paroxysm of hemoglobinuria with hemoglobinemia similar to the attacks of the syphilitic hemoglobinuric His health was otherwise excellent other forms of exercise were without effect there was no evidence of syphilis the blood did not give the Donath and Landsteiner reaction Another type of hemoglobinuria to be differentiated is the *chronic hemolytic anemia with paroxysmal nocturnal hemoglobinuria* (Micheli Marchiafava Witts Hamburger and Bernstein) This recently recognized disease known as the Marchiafava Micheli syndrome is characterized by paroxysms of hemoglobinuria persistent hemoglobinemia and anemia between attacks absence of relationship between exertion or chilling and the hemoglobinuria tendency of the attacks to occur at night reticulocytosis urobilinuria hemosiderinuria and incurability The hemoglobinuria of chronic malaria is also to be differentiated

Treatment —Various forms of therapy have been advocated autoserotherapy (Widal Abrami and Brissaud) graded cold foot baths (Salen) and administration of calcium chloride or calcium lactate These forms of treatment lack a rational basis and have not been demonstrated to compare in effectiveness with *antisyphilitic treatment* which Kumagai and Namba in a study of 14 patients have clearly shown to be the method of choice The writer has observed two patients who after thorough antisyphilitic treatment passed through two consecutive winters in New York without an attack In each case however the Wassermann and the Donath Landsteiner reactions remained positive though weakened The patients were treated with many arsphenamine injections mercury, iodides and bismuth This result corroborates the observations of Jones and Jones

NEPHRITIS

(*Bright s Disease*)

Introduction —In 1836 Richard Bright wrote 'It is indeed an humiliating confession that although much attention has been directed to this disease for nearly 10 years yet little or nothing has been done toward devising a method of permanent relief when the disease has been confirmed and no fixed plan has been laid down as affording a tolerable certainty of cure in the more recent cases '

A hundred years later we must amplify this apology of Bright with the equally humiliating confession that we today cannot cure the disease Furthermore its etiology and the mechanism of its progression or of spontaneous healing remain ob

scure Finally, the establishment of its diagnosis is at times impossible Hence a textbook discussion of Bright s disease must in part be indefinite in its statements unsatisfactory as to the statistical study of its incidence course and outcome, and speculative concerning its nature and the therapeutic measures to be employed Despite this apparent state of confusion and in all fairness to the innumerable studies devoted to the subject of nephritis it should be recognized that the importance of the relationship of certain infections to the onset and course of the disease has in a measure been clarified Also the development and application of *quantitative biochemical methods have contributed* enormously to our understanding of the pathologic physiology of Bright s disease upon which is based rational therapy

Definition —The term 'nephritis embraces a number of disease states of unknown etiology which may be acute or chronic and all of which are characterized by albuminuria and cylindruria and often by hematuria In addition to these signs of local renal dysfunction which are dependent upon bilateral nonsuppurative inflammatory or degenerative kidney lesions edema hypertension and nitrogen retention are frequently present Many of the manifestations both local and systemic are referable to disturbances in the vascular system

Classification —The present status of the classification of nephritis has been best described by Addis who says "Every student of Bright s disease constructs his own classification to meet his own individual interests and needs" In the absence of an etiologic basis for the classification of Bright s disease most terminologies have been of a descriptive clinical or anatomic nature Among the former various authors have divided the nephritides into those with or without edema while others have spoken of 'salt and water retention nephritis and 'nitrogen retention nephritis' These distinctions can no longer serve a useful purpose as we now know that these terms apply merely to different phases of a single disease process often encountered in the same patient The same may be said of classifications which attempt to differentiate various forms of nephritis by the predominance of manifestations resulting either from decreased blood flow through the kidney or from disturbances of filtration in the glomeruli and of reabsorption by the tubules Classifications based upon anatomic changes in the kidneys have fared better and are more generally accepted but they also have serious limitations Their greatest drawback is the fact that the pathologist not infrequently is unable to determine the nature or picture the course of the antecedent disease on the basis of the gross or microscopic findings present at death With the present limitations of our knowledge the chief aim in developing a classification is to find terms which may for the time being serve as labels *characterizing for the pathologist and clinician* the general aspects of Bright s disease in its various forms The following classification in simplified form is that which is in common usage today and the terminology must be recognized as being more specific than is justified by clinical and histopathologic knowledge In the light of the foregoing discussion it must be considered purely tentative

(*A*) Glomerulonephritis
  1 Acute form
  2 Chronic form
(*B*) Arteriolar nephrosclerosis
(*C*) Nephrosis
(*D*) Miscellaneous nephritides

Consideration of the various subdivisions of these larger classes will follow in their respective sections

GLOMERULONEPHRITIS

Etiology —Although the etiology of acute glomerulonephritis remains unknown all recent studies indicate clearly that a close relationship exists between certain infections and the onset of the disease In a vast majority of instances acute nephritis follows *infection of the upper respiratory tract* and in cases where careful bacteriologic and immunologic observations have been made it has become apparent that the hemolytic streptococcus (Group A of Lancefield) above all other organisms is of *prime importance* For example Longcope reported the presence of hemolytic streptococcal infection in 85 per cent of the patients with acute nephritis studied by him In the series of Seegal Lyttle E N Loeb and Jost the

sera in seventy six of eighty consecutive patients with acute nephritis contained a sufficiently high titer of antistreptolysin to be indicative of a recent hemolytic streptococcal infection From these observations and many similar ones we find that disease of the upper respiratory tract be it tonsillitis pharyngitis sinusitis the common cold grippe' peritonsillar abscess scarlet fever rheumatic fever etc is usually associated with streptococcal invasion when it is followed by acute glomerulonephritis Further evidence attesting to this relationship is the seasonal variation in acute nephritis found by Seegal *et al* The curve of incidence of acute glomerulonephritis in patients seen in the Presbyterian and Babies Hospitals in New York parallels closely that of streptococcal infection It should be pointed out however that it is not necessary for streptococcal infection to enter the body by the respiratory tract in order to have an associated acute nephritis for a number of cases probably more than are generally appreciated follow skin or wound infection by that organism In acute rheumatic fever, a disease in which the hemolytic streptococcus admittedly plays an important role about 15 per cent of the patients have either gross or microscopic hematuria In spite of this curiously enough only three of about 100 of Coburn s cases which were examined post mortem showed the presence of acute glomerulonephritis It seems likely that the renal bleeding so frequently encountered is not the result of glomerular inflammation but is merely another manifestation of the hemorrhagic diathesis in the rheumatic state On the other hand 25 per cent of patients dying with acute nephritis at the Presbyterian Hospital were shown at autopsy to have associated active rheumatic disease

That the streptococcus is not invariably *the infective agent* associated with the onset of acute nephritis seems apparent from the fact that most observers have a number of cases in their series which are thought to be associated with pneumococcal or gram negative coccal infections various pyogenic infections enteric fevers or with no demonstrable infectious process at all It must be kept in mind however that in many of these cases the presence of associated hemolytic streptococcal infection has not been eliminated by adequate bacteriologic or immunologic methods Despite this criticism it is certain that infectious agents other than the hemolytic streptococcus are occasionally associated with the onset of acute nephritis The disease picture in postpneumonic nephritis differs sufficiently from the usual type of acute nephritis to give this idea special support For example hypertension is usually absent even as uremia appears anemia is rapidly progressive and an increase in the antistreptolysin titer of the serum is absent

In addition to the factors already mentioned certain *chemical poisons* such as turpentine carbon tetrachloride cantharides arsenic and chromium salts cause renal irritation but this does not resemble the clinical or pathologic picture of acute glomerulonephritis On the other hand when sulfapyridine sulfathiazole and less frequently sulfadiazine have been administered hematuria oliguria nitrogen retention and edema may appear and at times these drug effects are indistinguishable from nephritis which might be induced by the underlying infection The confusion concerning the nature of the toxemias of pregnancy is so great that their consideration contributes little or nothing to a discussion of glomerulonephritis Bacterial endocarditis and other septic states are not infrequently associated with embolic and local inflammatory lesions in the kidneys and occasionally typical glomerulonephritis is superimposed on these lesions This is most frequently seen in cases of infection with *Streptococcus viridans*

The foregoing discussion has dealt with the *etiology* of *acute* glomerulonephritis in which the intimate association of this disease with hemolytic streptococcal infection has been stressed Nevertheless the severity and the course of the nephritis are entirely independent of the severity of the preceding infection The role of acute infectious processes in the etiology of *chronic* glomerulonephritis is much less certain although an exacerbation of the disease accompanies or follows intercurrent streptococcal infection not infrequently In the studies of Seegal *et al.* one or more exacerbations were seen in thirteen of a series of sixty eight patients observed from one to eight years In all bacteriologic or immunologic evidence indicated that the exacerbation may be initiated

by streptococcal infection but in five of twenty eight exacerbations no evidence of streptococcal infection was obtained The usual insidious onset and its lack of correlation with definite episodes of infection in striking contrast to the acute disease make it seem possible although not probable, that chronic glomerulonephritis may differ from the acute form not only in its mechanism and course but also in its etiology While certain investigators are of the opinion that the chronic form of glomerulonephritis results, as a rule, from the persistence or from frequent recurrence of overt or subclinical infection with the hemolytic streptococcus the evidence for this idea is not wholly convincing If hemolytic streptococcal infection be the usual cause of *chronic glomerulonephritis then the immune* response of the patient to that organism as measured by the anti streptolysin titer of his serum is different from that seen in the acute form The antistreptolysin titer in the acute form is elevated, frequently to extraordinarily high levels whereas in the chronic stage it is ordinarily low Outspoken streptococcal infection in these patients may cause the antibody titer to rise but not to the usual levels seen in acute nephritis Our ignorance concerning the etiology of chronic glomerulonephritis is well illustrated by the fact that the simple question of the frequency with which acute nephritis becomes chronic is answered by investigators in the field with the greatest divergence of opinion For example Addis, and also Longcope states that more than 40 per cent of patients suffering from acute nephritis develop the chronic form of the disease whereas Richter and others find the acute disease progressing in less than 20 per cent Still more confusing is the experience of Snoke This writer states that among a large series of children with acute nephritis studied by him in California the incidence of progression to the chronic form of the disease was 39 per cent In studying a similar group of children in Rochester New York he found progression from the acute to the chronic form in only 10 6 per cent

Mechanism of Glomerulonephritis—In the foregoing discussion the frequent association of infection with the onset of acute glomerulonephritis has been emphasized but this knowledge has not fundamentally advanced our understanding of the mechanisms involved in the production of the disease Thus many important and intriguing questions remain unanswered

Bacteriologic studies of recent years have shown conclusively that actual invasion of the kidneys by the infectious agent does not occur in acute or chronic glomerulonephritis except in the presence of bacterial endocarditis or sepsis Furthermore evidence points against the concept of immediate damage to the kidneys by the bacterial products because of the fact that acute glomerulonephritis almost invariably follows rather than accompanies the acute infection For example the acute nephritis of scarlet fever develops classically ten to twenty days *after the onset of the exanthem and a con*siderable time after the subsidence of the febrile reaction Similar time relationships obtain in acute nephritis following tonsillitis and other infectious processes In 1912 Escherich and Schick expressed the view that this time relationship suggested the possibility that glomerulonephritis was not induced by infection *per se* but by the immune reactions resulting from the infection Since that time Friedmann Longcope and others have come to a similar conclusion This concept may offer a satisfactory explanation for some of the obscure phenomena observed in the disease and is at the present time receiving support from laboratory investigation

Many attempts to produce in animals disease pictures analogous to acute and chronic glomerulonephritis in man have failed or have proved to be inconclusive In 1928 Masugi demonstrated that an antikidney serum produced by the injection of rat kidney emulsion into rabbits when injected into rats gave rise to acute or chronic nephritis These observations were confirmed by Arnott *et al* and have been greatly extended by Smadel and Farr The latter have shown that the injection of one two or three doses of rabbit antirat kidney serum into rats in the course of a few days induces acute nephritis Some of the animals so treated recover in about three weeks while others develop chronic nephritis which in the course of many months becomes associated with edema hypertension anemia

nitrogen retention and marked decrease in renal function The lesions in this latter group of animals treated with nephrotoxic kidney antisera bear a close resemblance to chronic glomerulonephritis in man These are striking and significant observations in asmuch as they demonstrate that a single insult to previously normal kidneys may initiate chronic progressive renal disease Smadel and Farr have recently found that in one strain of rats the course of the disease initiated by nephrotoxic immune serum may be altered by the amount of protein in the diet If this be restricted the nephritis tends to heal whereas if the amount of protein in the diet be increased the nephritis becomes progressive Thus the question of the possible deleterious effect of large amounts of protein stressed by earlier workers is again raised

If these observations concerning the nephrotoxic action of antikidney sera be applicable to man we can hypothesize that an infectious agent such as the hemolytic streptococcus produces within susceptible individuals nephrotoxic immune bodies These may then give rise to acute or chronic glomerulonephritis It is in relation to the latter form that we may find in these laboratory studies a possible explanation for those cases of progressive chronic glomerulonephritis in which most rigid clinical bacteriologic and immunologic studies fail to produce evidence for the persistence or recurrence of streptococcal infection to account for the relentless progression of the disease Unfortunately none of the experimental studies throws light on the obscure fact that most cases of chronic glomerulonephritis begin insidiously and without apparent relation to a recognized preceding infectious process The foregoing highly speculative discussion has no practical application but shows the trend of present day thought in relation to the mechanism of one of the commonest and most obscure of human maladies

Predisposing Factors—The role of sex in the susceptibility to glomerulonephritis is of interest in that there is a striking consistency in the preponderance of the disease among males in a ratio of approximately 2 1 No satisfactory explanation is offered for this unequal distribution

Age—Glomerulonephritis is essentially a disease of children and adults in the earlier decades of life the acute form being more common in children than in adults The Seegals and Lyttle reported that 70 per cent of their cases occurred before the age of twenty one The *incidence* of the disease in the acute form cannot be determined with any degree of accuracy because those patients without extrarenal symptomatology frequently do not come to the attention of a physician, and even when they do there is difficulty in establishing the diagnosis in these mild forms Among the cases diagnosed in general hospitals the Seegals and Lyttle found that among 35 000 admissions to medical wards the incidence was 0 02 per cent in northern hospitals while in hospitals of Louisiana and Texas the incidence was approximately the same being 0 47 per cent Since the disease in its chronic form so frequently begins insidiously the proof of its relatively early onset in life is best established by the age at death Of fifty seven autopsied adult cases at the Presbyterian Hospital thirty five died before the age of forty In a similar group but including children Fishberg reports that forty two of fifty four patients also died before the age of forty

Climate—As mentioned above the incidence of acute glomerulonephritis has been found by the Seegals to be independent of latitude These same investigators found that in the southern states as well as in the north the disease reaches its greatest incidence at that season of the year when disease of the upper respiratory tract and streptococcal infection are at a peak

Exposure to Cold—Many years ago the role of exposure to cold was thought to have great significance in relation to the onset of acute nephritis These instances became progressively fewer perhaps because the time interval between infection and the appearance of nephritis is better appreciated and because more careful bacteriologic and immunologic studies are made

Familial Susceptibility—Nine of fifty seven patients at the Presbyterian Hospital who came to autopsy because of chronic glomerulonephritis gave a family history of Bright s disease Ernstene reported a family in which six of ten children developed acute glomerulonephritis secondary to upper respiratory infection In spite of these facts the

familial incidence appears low in contrast to that present in arteriolar nephrosclerosis

Morbid Anatomy—At autopsy, the kidneys in *acute glomerulonephritis* are normal in size or slightly enlarged They are usually pale in color and may show punctate hemorrhages on their smooth surfaces On section the demarcation between cortex and medulla is well preserved and the glomeruli may appear as pale or hemorrhagic dots Microscopically, the earliest changes suggest an inflammatory lesion of the capillary loops in the glomeruli The endothelial cells are swollen and they proliferate and cause the glomeruli to become ischemic Later proliferation of epithelium outside of the capillary begins and polymorphonuclear cells accumulate in the glomeruli Thus the tufts appear rich in cells and in time tend to fill the capsular space completely In many of the glomeruli there is hemorrhage into the capsular space and also a deposition of fibrin The cells of the *tubules* show varying degrees of swelling and fatty deposit and their lumina are often filled with blood leukocytes and cellular debris The interstitial tissue tends to be edematous its capillaries are congested and scattered leukocytes are present The arterioles usually show little or no change but occasionally the glomerular inflammatory process is associated with an acute necrotizing arteriolitis

If acute glomerulonephritis heals there is usually no trace of it found at autopsy when death occurs from some other cause On the other hand if the process does not heal the disease progresses in the course of a few weeks or months to that intermediate phase which the clinician hesitates to call chronic but which is too prolonged and too continuously severe to be compatible with the acute stage This phase is known as *subacute glomerulonephritis* The kidneys are pale and swollen and constitute what were formerly called large white kidneys The surface is still smooth and has a fatty or grayish color Punctate or striate hemorrhages are still numerous and on section the cortex seems unusually wide and merges indistinctly with the medulla Microscopically the *glomeruli* show further increase in their cellular content or the capillaries are dilated with blood The capsular spaces contain blood and cellular debris and the capsule shows proliferation of the epithelial elements to form the so called ' epithelial crescents The cells of the *tubules* show further swelling and many have an accumulation of large fat droplets This degenerative change is associated with desquamation of the tubular epithelium There is an increase in cellular infiltration mostly lymphocytes in the *interstitium* and arteriolar changes are variable With further progression of glomerulonephritis the *chronic* form is reached which in a period of from one to forty years becomes terminal This chronic state is characterized by further gross and microscopic changes in the kidney The kidneys contract and are frequently reduced to one fourth their normal size The capsule is adherent and the surface pale and granular On section the cortex is markedly narrowed Microscopic examination shows progressive hyalinization and disappearance of the glomeruli Some of the tubules collapse and disappear though others become cystic Fibrosis of the interstitium is progressive and the arterioles show varying degrees of sclerosis In many instances the arteriolar changes become sufficiently striking to make it impossible to state from postmortem examination alone whether they are secondary to glomerulonephritis or whether the glomerular changes have followed arteriolar nephrosclerosis

ROBERT F LOEB

ACUTE GLOMERULONEPHRITIS

Clinical Picture—The classical' picture of acute glomerulonephritis is seen frequently in children and in young adults following infection with the *Streptococcus hemolyticus* The patient usually complains of hematuria puffiness of the face headache and a decrease in urinary output In the fulminating form of the disease edema may become generalized visual disturbances may occur hypertension may become extreme dyspnea marked delirium convulsions coma and death may ensue This dramatic sequence of events may be accompanied by fever anorexia vomiting anuria and varying degrees of nitrogen retention The foregoing description comprises perforce a com

posite picture of the more striking features of acute glomerulonephritis However it should be emphasized that the "classic" *i e* the unmistakable picture is rarely encountered in medicine More frequently one or more symptoms or signs dominate the disease For example in many patients with acute nephritis edema may be the only complaint or objective physical finding In others gross hematuria alone may attract attention to the disease A few complain of weakness or of backache In still others it is important to recognize that there may be no symptoms and no abnormalities on physical examination or they may be so mild and transient in nature that they entirely escape detection The diagnosis in these cases which are numerous is made possible only by the examination of the urine

In Richter s series *edema* was present in two thirds of the cases of acute nephritis It usually begins about the eyes and the face becomes puffy and pasty in appearance This is frequently most apparent when the patient awakes in the morning In many cases the edema involves the dependent parts and in some it becomes generalized occasionally being accompanied by effusion into the serous cavities it usually appears early in the disease though it may appear at any time The development of edema is due to at least three factors (1) A decrease in urine formation from a decreased blood flow through the ischemic glomeruli (2) Increased capillary porosity resulting from generalized capillary damage allowing the abnormal escape of fluid rich in protein to the interstitial spaces This in turn lowers relatively the effective osmotic pressure of the blood thereby tending to increase edema (3) Elevation of hydrostatic pressure by congestive heart failure contributing to edema formation in a number of cases It is of interest that the serum protein level in acute nephritis with edema is rarely reduced below 5.5 per cent although the albumin fraction may be significantly lowered

Variations in the elevation of *blood pressure* in acute nephritis are great The pressure may never exceed normal limits in the entire course of the disease On the other hand in about 25 per cent of the cases there is a moderate transient elevation of either the systolic or diastolic pressure or both In about 10 per cent the systolic pressure reaches 180 to 200 mm mercury and the diastolic pressure may be maintained well above 110 mm mercury In seven studied cases of postpneumonic nephritis Seegal has pointed out an absence of hypertension

In acute nephritis the elevation of blood pressure like the development of edema usually begins early in the disease but may appear some time after the onset Progressive elevation of pressure usually precedes the appearance of cerebral and cardiac symptoms The pressure may fluctuate widely from day to day suggesting that arteriolar spasm is probably the chief underlying mechanism involved In a few cases an extreme degree of hypertension is associated with an acute necrotizing arteriolitis

Closely allied with changes in blood pressure in acute nephritis are the *cerebral manifestations* of the disease When the pressure begins to rise rapidly there may develop severe headache nausea and vomiting somnolence or mental confusion Finally generalized clonic convulsions may occur These episodes were present in 10 per cent of the series studied at the Peter Bent Brigham Hospital Their mechanism is not understood but they are not dependent upon nitrogen retention They are probably due in part to cerebral ischemia associated with arteriolar spasm and hypertension and with more or less cerebral edema Convulsions may occur once or they may recur at frequent intervals as in a status epilepticus Death is not uncommon following recurrent convulsive seizures *Visual disturbances* occur with these attacks of so called hypertensive encephalopathy The commonest of these is blurring of vision Amaurosis is transient in nature and occurs in about 2 per cent of hospital cases The *eyegrounds* in acute nephritis are usually normal but many changes may occur Papilledema is not unusual and is most frequently seen with elevation of blood pressure with or without hypertensive cerebral episodes The retinal arteries appear pale and narrow when hypertension is marked Hemorrhages into the retina are not unusual and are probably an other manifestation of general capillary damage in acute nephritis Exudate is rarely present Occasionally the complete picture

of edematous disks vascular changes hemorrhages and exudate is seen in the fundi of patients with acute nephritis The author has seen one patient who had acute nephritis associated with massive edema hyper tension nitrogen retention a series of epileptiform convulsions papilledema retinal hemorrhages and macular stars of exudate Fourteen years later that individual had no evidence of nephritis or hypertension and his eyegrounds were normal but for slight pallor of one optic disk While such cases are distinctly unusual they occur with sufficient frequency to show that these extreme changes are at times reversible

The *heart* frequently suffers to a greater or lesser degree in the majority of cases of acute nephritis Whitehill Longcope and Williams found that myocardial failure varies in its severity in direct proportion to the severity of acute nephritis Thus fifty three of fifty nine patients with severe nephritis had some evidence of cardiac insufficiency Among mild cases twelve of thirty five had some circulatory disturbance The abnormalities encountered range from mild electrocardiographic disturbances without symptoms to extreme congestive failure associated with dyspnea orthopnea tachycardia gallop rhythm pulmonary congestion and elevation of venous pressure A number of patients with acute nephritis die from cardiac insufficiency Fatal insufficiency may be precipitated by the exertion associated with convulsive seizures

With the progressive development of massive edema fluid may collect in the pleural cavities and the *lungs* may show the presence of rales at the bases The patient may become dyspneic because of decreased lung elasticity When cardiac insufficiency supervenes frank pulmonary edema as has been mentioned may occur Edematous patients not infrequently develop secondary bronchopneumonia

The presence of *anemia* early in the course of acute nephritis is distinctly unusual and when present it should arouse suspicion of a chronic process with a superimposed acute exacerbation When acute nephritis persists over a period of many weeks particularly if renal bleeding plays a prominent role varying degrees of secondary anemia may develop The white cells in acute nephritis are normal unless infection complicates the picture

The *urine* volume in acute nephritis may be normal throughout the course of the disease On the other hand it may decrease in amount abruptly at the onset of the disease and may present either a smoky or definitely bloody appearance Anuria occurs in about 5 per cent of hospitalized patients with acute nephritis and is a serious manifestation The oliguria encountered may not be associated with outspoken edema for some time although it represents retention of fluid in the interstitial spaces The reasons for the appearance of oliguria and anuria are those mentioned in the discussion of edema In addition it seems that arteriolar spasm with a resulting decrease in blood flow through the kidneys is an important contributing factor This idea receives support from the fact that the termination of anuria and the gratifying appearance of diuresis may be sudden and too rapid to be explained by the subsidence of inflammatory lesions There is usually little interference with the ability of the kidneys to concentrate in acute nephritis and consequently the *specific gravity* of the urine is as a rule maintained at normal levels *Albumin* is regularly present in the urine in acute nephritis and the diagnosis of the disease is untenable in its absence The amounts present are extremely variable and the course and prognosis are entirely independent of them Albuminuria is frequently the last manifestation of the disease to disappear in the process of healing

Hematuria either gross or microscopic is present in acute glomerulonephritis with such regularity that the disease in the classification of Addis has been termed acute hemorrhagic nephritis In the absence of gross or microscopic hematuria the diagnosis of acute glomerulonephritis must be held in doubt The amount of blood in the urine is extremely variable In about 40 per cent of the cases gross hematuria is recognized This symptom is present as a rule for only a few days but may recur from time to time in the course of the disease Microscopic hematuria often persists for months and may continue long after routine examination fails to reveal albuminuria although as stated above in other cases al

bumin is the last to disappear A moderate number of leukocytes are usually present in the sediment but frank pus is not encountered Casts of various kinds are always present in acute nephritis Most characteristic and important diagnostically, if present among these formed elements are red blood cell casts Nevertheless other cellular casts granular hyaline and waxy casts may be present in varying numbers

Renal function as measured by tests other than routine urine examination is normal in about 50 per cent of patients with acute glomerulonephritis In others varying degrees of nitrogen retention are observed but the blood urea nitrogen rises above 100 mg per cent in less than 5 per cent of the cases The higher values are usually associated with oliguria and hypertension but it should be emphasized again that the convulsions of hypertensive encephalopathy occur independently of azotemia and may be fatal without any nitrogen retention When nitrogen is retained in appreciable amounts there may be a decrease in the rate of excretion of phenolsulfonphthalein and the urea clearance test may show a striking decrease in kidney function Accompanying these marked changes there may be retention of creatinine and uric acid and the development of acidosis due to phosphate and sulfate retention Only 2 or 3 per cent of patients with acute nephritis die of true uremia. The marked depression of renal function occurring in a number of cases is not necessarily associated with progressive disease or death On the contrary it is usually a reversible disorder which may disappear in the course of a few days as blood flow through the glomeruli increases

Diagnosis —In the classic case of acute glomerulonephritis diagnosis affords no difficulty However when albumin casts and red blood cells appear in the urine in unmistakable but small quantities after or during an acute infection with the hemolytic streptococcus or other organisms and unaccompanied by edema hypertension or nitrogen retention the problem becomes more difficult Certain authors escape this diagnostic difficulty by applying the term focal nephritis to these cases In the writer s opinion this does not advance our knowledge or clarify the situation If the urinary findings described persist over periods of one or two weeks it seems likely that acute glomerulonephritis is present If the microscopic hematuria casts and albumin disappear in a shorter time it is best to admit that the diagnosis remains in doubt and that the findings may result from increased permeability of renal capillaries due to irritation" passive congestion embolic phenomena or to causes unknown It should be emphasized that numerous blood pressure determinations repeated urine examinations and a careful record of body weight aid tremendously in detecting transient abnormalities which may establish the diagnosis in mild cases

The difficulty in establishing a diagnosis in borderline cases is emphasized by the studies of the urine in scarlet fever carried out by Lyttle This investigator applied to sixty-eight patients with scarlet fever Addis quantitative method for the determination of protein casts and cells in the urine He found in all the cases that a moderate transient increase in all elements above accepted normal levels occurred between the eighth and the forty fifth day after the onset of the disease Lyttle found similar changes in the urine following other forms of streptococcal infections but not with any regularity after infection due to other organisms To state on the basis of these findings that all patients develop nephritis after scarlet fever or other streptococcal infections seems to Lyttle as well as to the author unreasonable but whether the difference between this micronephritis or renal irritation and true outspoken acute glomerulonephritis is qualitative or quantitative cannot be settled at the present time The difficulty in differentiating acute glomerulonephritis and the effects of certain sulfonamide drugs upon the kidney has already been emphasized

In cases of acute glomerulonephritis in which gross hematuria persists particularly when associated with dysuria and pain in one or both costovertebral angles urologic aid may become necessary to establish the diagnosis If the amount of albumin in the urine is massive and red blood cell casts are present and if edema or hypertension is found the diagnosis is simplified In the absence of these signs it may be necessary to resort to cystoscopic examination or in

travenous pyelography to eliminate the possibilities of tumor stone tuberculosis pyelonephritis etc

The differentiation between *orthostatic albuminuria* and acute glomerulonephritis arises only in those patients who have virtually no red cells in their urinary sediments In the absence of other signs and symptoms of nephritis and in the presence of albuminuria which appears only in the erect position a diagnosis of orthostatic albuminuria becomes justifiable with repeated observations particularly when occurring in a thin child or in an adolescent

The differential diagnosis between acute and chronic glomerulonephritis is of great importance because of the difference in prognosis Nevertheless this is at times impossible particularly when an exacerbation of chronic nephritis follows an acute infection and resembles in all respects the disease in its acute form In this situation only a record of a urine examination just prior to the onset of the symptoms or the presence of signs of advanced renal disease will help to distinguish between the acute and chronic forms In the absence of these aids the diagnosis becomes dependent upon the subsequent course

In embolic acute nephritis in which there are manifestations only of albumin casts and hematuria unless diffuse glomerulonephritis supervenes the diagnosis is dependent upon the demonstration of blood stream infection by culture

Prognosis —Less than 5 per cent of patients with acute glomerulonephritis die of this disease In fatal cases death results from one or more of the following causes (1) hypertensive encephalopathy associated with convulsions (2) cardiac decompensation frequently terminating in pulmonary edema (3) uremia and (4) bronchopneumonia or sepsis

Most patients who are attacked by acute glomerulonephritis recover completely although authorities differ widely as to the actual percentage In children it is generally conceded that the prognosis is particularly good The course of the disease may last but a few days or it may persist for more than a year and yet terminate in recovery Perhaps the most frequent duration of acute nephritis among hospitalized patients is about two months It is important to recognize that the duration of acute glomerulonephritis and the ultimate outcome in terms of healing or of the development of chronic nephritis are independent of the severity of the preceding infection and the apparent severity of the disease as measured by the degree of albuminuria hematuria hypertension or edema In other words the clinical course in one patient while distinctly alarming may terminate favorably within two or three weeks whereas in another patient an apparently benign clinical course may progress to fatal chronic nephritis Although it is apparent that the ultimate outcome in acute nephritis cannot be predicted the impression has been gathered that healing is most frequent when the onset of the preceding infection is accompanied by severe constitutional reaction At this point it should be emphasized that when a patient recovers completely from acute glomerulonephritis *i e* when the urine becomes free from albumin red blood cells and casts permanent immunity for reasons unknown is almost invariably established regardless of the frequency or severity of subsequent streptococcal infections

Treatment —In the absence of specific therapy the treatment of nephritis must be largely symptomatic and in so far as possible based on recognized physiologic or biologic principles *Bed rest* is the first and most important therapeutic indication Ideally the patient should be kept in bed until all symptoms and signs of acute nephritis have disappeared Practically bed rest should be continued until all the general manifestations have disappeared In spite of the fact that small amounts of albumin and a few red blood cells may continue in evidence in the urine for six months or a year after the onset of the disease it is usually impossible to keep the patient at rest for this length of time If the urinary findings persist after two months and the extrarenal signs have vanished and if the erythrocyte sedimentation rate has returned to normal the patient may be allowed up If this change is associated with an increase in albuminuria or hematuria further bed rest is indicated Exposure to chilling and exposure to individuals with upper respiratory infection should be avoided The *dietary restrictions*

in acute glomerulonephritis depend to a large extent upon the presence or absence of oliguria edema hypertension and nitrogen retention Even in the absence of these findings the *restriction of sodium chloride* or bicarbonate is indicated as sodium salts constitute the chief 'building block of edema fluid When the course of the disease proceeds rapidly in the direction of the fulminating picture previously described limitation of food and fluids to 800 cc of fruit juices or weak tea or 25 per cent glucose solution a day may aid in preventing the rapid accumulation of fluid and the development of hypertensive encephalopathy or cardiac insufficiency This regime should not be continued for more than three or four days In milder forms of the disease a salt poor diet containing perhaps 50 to 60 Gm of protein a day seems to be the only dietary indication There is however no sound clinical evidence to suggest that the amount of protein in the diet in any way influences the course or outcome of acute glomerulonephritis

Medication—No drugs are indicated in the treatment of acute nephritis except in the presence of hypertensive encephalopathy Here the daily administration of 15 to 30 Gm of magnesium sulfate by mouth and the slow intravenous administration of 25 cc of 10 per cent olution of the same salt may have some effect in lowering the blood pressure and in preventing convulsive seizures When these measures fail the intravenous injection of hypertonic glucose solution morphine venesection and lumbar puncture are resorted to but usually without striking benefit Diuretics have no place in the treatment of acute nephritis and at times appear to add to the renal damage Therapeutic hyperthermia is distinctly dangerous in that it not infrequently contributes to cardiac insufficiency The use of diathermy over the renal area has been recommended in recent years but in the writer s experience it has been entirely without effect The *surgical treatment* of acute nephritis consists in decapsulation of the kidneys on the theory that the resulting decrease in tension permits greater blood flow Most reports suggest that the results obtained by this method in the treatment of anuria are disappointing The procedure has no justification in conditions other than "renal shut down'

In view of the intimate relation between streptococcal *infection* and the etiology of acute nephritis it is logical to eliminate all active and potential foci If sinusitis or mastoiditis is present surgical treatment should not be delayed When nephritis follows tonsillar infection these structures should be removed when the general manifestations of nephritis have disappeared In other cases tonsillectomy may be postponed until later *in convalescence Acute exacerbations of* nephritis frequently follow tonsillectomy and are usually characterized by an increase in hematuria These flare ups of the disease subside as a rule in a few days This radical point of view toward tonsillectomy is justified only by the fact that many capable observers still stress the relationship between persistent infection and the progressive nature of the nephritic process in many cases Further study may show however that this relationship is coincidental rather than causal and the writer from his experience must confess that he ha never been convinced that tonsillectomy has significantly altered the outcome of acute glomerulonephritis

In view of the close association of streptococcal infection and acute glomerulonephritis the role of *sulfonamide therapy* deserves consideration It has recently been demonstrated that sulfanilamide given in the course of acute glomerulonephritis does not increase the intensity of the nephritic process Evidence suggesting a specific effect of the drug on the disease is however not convincing Nevertheless sulfanilamide should be administered if active hemolytic streptococcal infection continues after the appearance of the nephritis Sulfapyridine sulfathiazole and sulfadiazine cannot at the present time be considered the drugs of choice because of their known effects upon the kidney

Robert F Loeb

CHRONIC GLOMERULONEPHRITIS

Clinical Picture—The clinical picture of chronic glomerulonephritis is even more variegated than is that of the acute form of the disease Only a small minority of cases

is observed to develop from an attack of typical acute glomerulonephritis following an acute infection with the hemolytic streptococcus The majority of patients with chronic glomerulonephritis seek medical aid because (1) they have noted the insidious onset of edema primarily dependent in nature (2) they complain of recurrent headaches which are usually associated with hypertension (3) they have developed dyspnea which may be exertional or paroxysmal in nature and is also as a rule related to the presence of hypertension or (4) they have been discovered on routine examination to *have albuminuria This last group* comprises about 10 per cent of a series studied at the *Presbyterian Hospital Probably* weakness lassitude and loss of weight are the commonest of all symptoms but they are characteristic of chronic disease in general and thus lose special diagnostic significance

To cases where albuminuria and cylindruria alone determine the presence of chronic glomerulonephritis the term *latent nephritis* has been applied It is reported by a number of observers that a few patients with this quiescent form of the disease recover completely Far more frequently another course is followed Either with or without persistent or recurrent infection the disease in a number of these patients becomes active as determined by an increasing number of red blood cells excreted in the urine With this *increase in activity* there may appear any or all of the symptoms and signs characteristic of outspoken acute nephritis and the patient may die with convulsions or in true uremia Autopsy in these instances shows the presence of subacute nephritis This active phase of chronic nephritis may on the other hand again become latent, only to recur repeatedly In the following months or years hypertension anemia nitrogen retention and finally the full blown picture of uremia will terminate the disease unless the course be intercepted earlier by fatal cerebral *hemorrhage or* cardiac failure Other patients enter the *nephrotic state* described fully in conjunction with the nephroses and remain water logged for months or years These patients either die of intercurrent infection *e g* bronchopneumonia or their edema subsides When the edema decreases the disease may again become latent with little or no demonstrable impairment of renal function More *frequently however*, the loss of edema presages further advance of the disease As fluid vanishes the blood pressure in time begins to rise and the development of this *hypertensive phase* is often accompanied by severe headaches and varying degrees of *cardiac insufficiency* Progressive failure in renal or cardiac function or both then terminates the disease Many patients pass directly into the hypertensive phase without ever having had more than minimal edema of the ankles or face In a few patients the advance of chronic nephritis is so gradual and so devoid of symptoms that a patient comes first to the ophthalmologist complaining of blurred vision and then in the course of a few weeks dies in uremia

The patient with chronic glomerulonephritis on inspection not infrequently presents the picture of health In the nephrotic stage striking pallor accompanies the edema and probably results in part from wide separation of skin capillaries by edematous tissues In the terminal stages of chronic nephritis the patient presents a classic appearance He looks weary and pallor now due to anemia is accompanied by a characteristic sallow tint His rest is frequently disturbed by muscle cramps The skin becomes dry and atonic and in advanced uremia in the colored race more frequently than in the white is often covered by the so-called urea frost" Mild exophthalmos commonly appears with the advance of hypertension The breath develops a typical odor wrongly termed uriniferous Fibrinous pericarditis occasionally accompanied by fibrinous pleurisy appears in about 40 per cent of patients within two weeks of death Muscular twitching occasionally due to tetany *occurs with* great regularity and when acidosis is marked hyperpnea appears Pruritus leads to uncontrolled scratching by the stuporous patient Bleeding from the nose or gastrointestinal tract is a common terminal manifestation In addition to dyspnea and Cheyne Stokes breathing probably the most distressing subjective symptoms are those of complete gastric intolerance coupled with thirst Most patients die in coma but fifteen of fifty seven patients at the Presbyterian Hospital who died of this disease and were examined postmortem had had terminal gen

eralized convulsions and in nine pulmonary edema was present

The frequency with which *edema* appears in chronic glomerulonephritis is indicated by the fact that among sixty seven patients who died of the disease at the Presbyterian Hospital this manifestation was recorded at some time in the records of fifty seven It was mentioned as being facial in twenty seven instances and dependent in forty nine The edema which appears during acute ex acerbations is probably caused by the fac tors mentioned in the discussion of acute nephritis In the nephrotic phase the most important factor is a decrease in the albumin fraction of the serum proteins The reader is referred to the section on nephrosis for further information

In all of fifty seven patients with chronic glomerulonephritis examined postmortem at the Presbyterian Hospital *hypertension* was present On the other hand in the so called latent phase of the disease the blood pres sure may remain normal for many years For example in a patient seen in the Presby terian Hospital with edema hypertension nitrogen retention albuminuria and hem aturia the blood pressure now twenty two years later is normal and only albuminuria and cylindruria persist In another patient refused a position because of albuminuria fifteen years ago the blood pressure is nor mal despite the facts that edema and head ache required hospitalization eleven years ago and that the patient has had many subsequent respiratory infections due to the hemolytic streptococcus Thus it is apparent that hypertension while it may occur early in the disease at which time it fluctuates considerably is a relatively constant finding only as chronic nephritis progresses to its termination The height of the level attained is variable but involves both the systolic and *diastolic pressures In thirty nine of a* group of fifty-seven studied postmortem the systolic pressure was above 190 mm mer cury and in sixteen of the group it reached levels higher than 230 mm mercury

Disorders of the *heart* appear late in the course of chronic nephritis and are associ ated with the presence of hypertension In a patient in whom the disease progresses rapidly hypertension and cardiac insuf ficiency may develop within a few months after the apparent onset of the disease On the other hand chronic glomerulonephritis may be present for many years before any elevation of blood pressure or impairment of cardiac function takes place Cardiac hyper trophy and dilatation may develop slowly or rapidly after the appearance of hyper tension but neither the degree of cardiac embarrassment nor the size of the heart can be directly correlated with the height of the arterial pressure or with its duration Hence it is fair to suspect that factors other than work contribute to cardiac hypertrophy in chronic nephritis

In the series of patients studied post mortem at the Presbyterian Hospital more than 90 per cent complained of dyspnea This was usually exertional in nature but about 20 per cent of the patients also com plained of paroxysmal dyspnea and had terminal pulmonary edema In a number of patients even in the absence of frank signs of left ventricular insufficiency there may be elevation of the venous pressure which contributes to edema In the uremic state gallop rhythms are frequently heard and as has been stated above about 40 per cent of the patients have a sterile fibrinous or serofibrinous pericarditis There are no char acteristic electrocardiographic changes asso ciated with the cardiac insufficiency of chronic nephritis but left ventricular pre-ponderance naturally appears at times The heart at postmortem weighed more than 400 Gm in 70 per cent of the Presbyterian Hospital cases thus corresponding to the enlargement found on x ray examination

The *cerebral* manifestations in chronic nephritis should be considered primarily in conjunction with hypertension Many pa tients without edema or hypertension com plain of headache and in view of its fre-quency without renal disease it seems likely *that it is often falsely attributed to neph* ritis About 30 per cent of patients with chronic glomerulonephritis are entirely free from headache while in the remainder it may be mild and infrequent even though hypertension be present On the other hand almost daily headaches torture some pa tients for long periods of time they may occur at any time of day and are accentu ated by fatigue Sometimes pain is present on awakening in the morning and disappears

a few hours later The mechanism of this distressing symptom is not understood particularly as it comes and goes without necessarily being associated with any change in arterial tension Classic hypertensive encephalopathy culminating in convulsions is rare and usually fatal in chronic nephritis The epileptiform seizures seen in the terminal stages of the disease are probably related to renal failure with the retention of substances leading to increased irritability of the nervous system

The majority of patients with chronic glomerulonephritis complain of some *visual disturbance* late in the disease This is usually characterized by blurring of vision and less frequently by blindness Ophthalmoscopic examination reveals arteriolar changes in most patients in whom hypertension has been established for some time Edema of the optic disks or the retinae appears in more than half the patients and exudate and hemorrhage have approximately the same incidence These changes in the fundi may occur singly for years and may vary in degree from time to time, but when all the changes enumerated are present the duration of life is as a rule less than two years

The *blood* in chronic glomerulonephritis may remain normal for many years but anemia finally develops in most patients Thus in the Presbyterian Hospital series the red blood count was less than 3 000 000 per cubic millimeter in about 60 per cent of the patients in advanced stages of the disease The color index varied between 0 8 and 1 2 in 70 per cent In other cases perhaps associated with bleeding the anemia is definitely hypochromic while very occasionally it is hyperchromic in type Isaacs has found that the bone marrow in chronic nephritis shows that there is a tendency for hematopoiesis to be arrested in the erythroblastic stage The development of anemia is usually gradual and yet the writer has seen the hemoglobin fall more than 30 per cent in twelve days without hemorrhage without increase in bilirubinemia without increase in reticulocytes and in the face of repeated transfusions The white blood cells show no particular change from normal The hemorrhagic diathesis seen in uremia results from an increase in capillary fragility Bleeding from the nose or gastro intestinal tract or purpura develops terminally in about two thirds of the patients The changes in the serum proteins and lipoids in the nephrotic phase of glomerulonephritis are described elsewhere, inasmuch as they are qualitatively and quantitatively the same as in true nephrosis In advanced glomerulonephritis the serum proteins may be normal or decreased in amount
